Q.—(1) How is it that the rather prolonged boiling of fruit in making jam does not destroy vitamin C? Is it that vitamin C is not so easily destroyed by heat as we used to believe? (2) Is it the case that fruit bottled by ordinary domestic methods retains its vitamin C content? (3) Can you recommend any publications giving up-to-date information on the present knowledge of vitamins in a compact and practical form useful to general practitioners and dietitians?

A.—The stability of natural vitamin C in ordinary domestic cooking is now known to be much greater than was previously believed. For instance, in the cooking of leafy vegetables by boiling, or in the stewing of fruits, although extraction into the cooking liquor is usually of the order of 50%, destruction of the vitamin is frequently less than 10%. It must be remembered that in all boiling, stewing, and bottling processes oxidation by direct contact of the material with air is largely prevented by the protective layer of steam produced in the cooking process. Oxidation of vitamin C is, however, accelerated if (1) the enzymes present in the fruit or vegetables are liberated (for instance, by damage to the plant tissue before use) and allowed to act before being destroyed by heat; (2) free access of oxygen is permitted while the material is still hot (as shown by the rapid destruction of the vitamin when vegetables are "kept hot"); (3) cooking is carried out in a markedly alkaline medium (this is unusual in domestic practice even when soda is used for green vegetables); or (4) contamination with metallic ions such as iron or copper occurs. In making jam it is possible to control all the above factors so that the destruction of vitamin C is negligible, but if such control is not exercised, then naturally a proportional loss of the vitamin is to be expected. Similarly, it is possible to retain a high percentage of the vitamin C content of fruit on bottling by approved domestic methods.

While it is difficult to recommend publications on vitamins which are compact, practicable, and at the same time up to date, the following should be found useful: Harris, *Vitamins in Theory and Practice*; Fixsen and Roscoe, "Tables of the Vitamin Content of Human and Animal Foods," II (1940), *Nutrition Abstracts and Reviews*; Booher, Hartzler, and Hewston, *A Compilation of the Vitamin Values of Foods in Relation to Processing and Other Variants*; Circular No. 638, May, 1942, United States Department of Agriculture; Oliver, "Ascorbic Acid Values of Fruits and Vegetables for Dietary Surveys," *Chemistry and Industry*, 1943, vol. 62, No. 16, pp. 146-8; Harris, "Vitamins," *The British Encyclopaedia of Medical Practice*.

#### INCOME TAX

##### Accounts for Two Years: Contributions to War Damage

B. J. states that the practice audit was not done for two years, but the income-tax assessments were increased. Secondly, two houses are mortgaged; can a claim be made on the mortgages for a share of the war damage contribution and income tax?

•• (1) The Income Tax Acts assume that yearly accounts are prepared and do not provide for cases where the account covers two years. B. S. should get in touch with his inspector of taxes and suggest that the adjusted profit shown by the two-years account should be regarded as earned evenly over the two years and the income-tax assessments adjusted on that basis.

(2) The position as regards war damage contributions depends on several conditions. These are set out in a pamphlet (known as Form W.D.7.) which can be obtained from the Regional Office of the War Damage Commission. Income tax can be deducted at the

standard rate from mortgage interest paid to a private concern. If it is paid to a building society the normal practice is for a deduction to be made from the tax assessed under Schedule A on the property to give the appropriate relief; the inspector of taxes can say whether this has been done.

#### "Pay as You Earn"

H. M. is assessed under Schedule E and has received a notice that the collector has been authorized to accept 5/6ths of the tax charged for the year 1943-4, because as from April 6 next he will be assessable under the new system on the current year's basis and pay tax currently by deduction.

.\* This is correct. It is true that H. M. has been assessed for a year's income for each year of his employment and that at one time the assessments were on the current year's basis. But he has not yet accounted for tax on his earnings from April 5, 1943, and when April 5, 1944, is reached would normally be owing a further seven months' tax—the deductions for the 1943-4 tax having started in November, 1943. So H. M. will in fact benefit by the cancellation of seven months' tax, because once the deductions have started after April 5, 1944, he will be up to date instead of being seven months in arrears with his payments.

#### Post-war Credit

I. H. has received a notice, the final figures of which are:

	£	s.	d.	£	s.	d.	
Earned income relief .. .. .	19	7	0				
Personal allowance .. .. .	20	0	0				
Amount of allowances ranking for post-war credit .. .. .				39	7	0	
Tax on above .. .. .	£23	7	0	@ 6/6 =	7	11	9
	£16	0	0	@ 10/- =	8	0	0
					15	11	9

He suggests he should not pay income tax on his post-war credit.

.\* The figures are not perhaps set out as clearly as they might have been. What it is intended to convey is that £39 7s. is the amount on which the income-tax post-war credit is due, and that that credit is £15 11s. 9d.

#### Earnings of Married Woman

D. G. is married to a professional man. Last year she earned £89 4s. 6d. for part-time clinic work, and £18 19s. 10d. income tax has been charged on those earnings. Is that correct?

.\* We assume that D. G.'s husband has had the maximum earned income relief (10% on £1,500 = £150), and that the assessment is made as for the year ended April 5, 1943. On that basis the assessment should be:

	£	s.	d.
Amount of income .. .. .	89	4	6
Wife's earned income allowance .. .. .	80	0	0
Balance .. .. .	9	4	6
Tax @ 10/- in the £ .. .. .	4	12	3

(The special allowance for the wife's earnings was increased from £45 to £80 for the year ending April 5, 1943, and following years.)

## LETTERS, NOTES, ETC.

### Horse Transport and Diarrhoeal Diseases

JOHN FOLEY, B.Sc. (London, W.C.2) writes: While, as you point out in the editorial on the increase in diarrhoeal diseases among children during the war (Jan. 29, p. 155), there are many factors contributing to this increase, there is another which goes unnoted—the increased use of horses in the larger towns. It would be of interest if some statistician would compare the changes in the deaths due to diarrhoeal diseases with the reduced use of motor cars and the rise in the use of horse transport during these war years. It is clear from quite superficial study that the increased amount of horse dung deposited in the streets of the towns cannot, owing to labour shortages, be disposed of as quickly and effectively as the smaller peacetime quantity. The death rates have increased in just those places where there is the greatest increase in the change over from petrol to horse transport—i.e., the larger towns. Some years ago, before the war, I had occasion to meet many of the paediatricians attached to the London hospitals. There were often comments that the incidence of diarrhoea and vomiting in infants had fallen considerably since the virtual replacement of the horse by the internal combustion engine. Should some parallel be clearly shown in the suggested comparison, then the authorities would have to consider the lives risked and lost in the transport across the seas of fuel necessary to enable commercial users of horses to revert to mechanical power, and their value compared with those of the children dying from diarrhoeal diseases carried by flies breeding on the horse dung on the roads.

### Hereditary Cold Fingers

Dr. E. C. CURWEN (Hove) writes: In the reply to a question on this subject in the *Journal* of Jan. 15 (p. 103) it is stated that drug treatment is unlikely to be effective. I have a patient who for the last 7 years has been on a regular daily dose of benzedrine (15 to 20 mg.) on account of constitutional lethargy and somnolence. Previous to taking this drug he used to suffer from numb, white, painful fingers when the body as a whole became chilled. During the time that the benzedrine has been administered there has been no return of the finger condition at all, though, curiously enough, he finds cold weather more difficult to endure than he did before.

### Examining School-children

Dr. V. V. BROWN (Bristol) writes: At the moment, when there is so much talk of education and of school medical services, I am very disturbed by information which I was given by a school-master recently. He is on the staff of a school with 500 pupils, and he tells me that prior to the visit of the school medical officer the pupils' height, weight, and visual acuity are recorded by members of the teaching staff. Although I have the greatest admiration for the teaching profession, I feel sure that, even with the best of intentions, these records are not likely to approach the required standard of accuracy unless they are completed by a member of the medical or nursing profession. Is it reasonable to suppose that a school-master would take the necessary care or that he would be sufficiently conscious of the importance of these records?

.\* It is tentatively suggested by Dr. Margaret L. Foxwell in an article on the School Ophthalmic Service in *Public Health* (August, 1943) that school-teachers should carry out visual acuity tests because, among other reasons, they are most likely to "notice such habits as blinking, head tilting, periodic squints. . ."

### Backache and Renal Disease

Dr. E. WEATHERHEAD writes: In the article by four medical officers of the Air Services in the *B.M.J.* of Jan. 8, entitled "Influenza 'A': Account of a Minor Epidemic," the following rather surprising statement is made: "Severe low backache was experienced by two or three patients, and had there not been an epidemic of influenza this might easily have been mistaken for a renal condition" (italics mine). We are not told of any other symptoms in these patients suggestive of renal disease. Surely, backache—which is generally acknowledged to be the commonest of all symptoms, occurring in an extremely wide variety of conditions—takes a very minor place in renal disease except in "Newspaper Medicine" or advertisements in which the sufferer's attention is generally directed to his kidneys. The other, and far more important, symptoms and signs of nephritis or other form of kidney disease would at once enable the physician to distinguish the condition from influenza.

### Speculation

Dr. A. N. MACBETH writes: Your inquirer (Nov. 20, 1943, p. 666) might be informed that the ordinary myxoedematous thyroid is refractory to thyrotrophic stimuli, the ordinary myxoedema being a primary failure at the thyroid level. Sharpey-Schafer finds that some cases of ordinary myxoedema show a residual response to the trophic factor, but this can be elicited only by very high doses. The myxoedema that occurs secondarily to pituitary depression is rarer, and it is to this type alone that his queries could be applied. A recent issue of the *Journal of Mental Science* refers to the occurrence of material increases of pituitary secretion of one kind or another following electrical convulsive therapy. Such increase may of course be confined to cases whose original output was low.

### Unusual "Deficiency" Diseases in Barbados

Dr. M. LATTEY (St. Georges, Bermuda) writes: While working in Barbados I saw many deficiency diseases, and found two conditions which I have not seen described anywhere. I should like to know if anyone else has seen them. The first I have called "deficiency nephritis." I saw it only in children, and it is characterized by generalized oedema, and by large quantities of albumin and hyaline and granular casts in the urine. Hospitalization alone, on the usual hospital diet, had no effect on the disease, even after two weeks, but when thiamin chloride was given the condition cleared up in a few days. This was presumably a form of beriberi, differing in that I have never seen renal lesions described in beriberi. Albuminuria is seen in protein starvation, but if this were protein starvation it would presumably have been improved by the hospital diet. The second condition was a frequent accompaniment of the angular stomatitis of vitamin B deficiency, and consisted of sores at the end of the prepuce. These sores were similar in appearance to the sores at the corners of the mouth, were usually at the same stage of development, and were likewise healed by the administration of vitamin B complex. The Kahn test was negative in all cases in which it was done.

## SOME OBSERVATIONS ON HOSPITAL DUST WITH SPECIAL REFERENCE TO LIGHT AS A HYGIENIC SAFEGUARD

BY

LAWRENCE P. GARROD, M.D., F.R.C.P.

Professor of Bacteriology in the University of London; Bacteriologist to St. Bartholomew's Hospital;  
Pathologist to an E.M.S. Hospital

Dust has been recognized as a vehicle of infection for many years, but preoccupation with "droplet" spread has obscured its true importance until recent times. The first of a series of modern studies revealing the actual infectivity of dust was that of Cruickshank (1935), who found that haemolytic streptococci could readily be cultivated from the air and dust in the burn wards of the Glasgow Royal Infirmary, where most of the patients were infected by these organisms. Elizabeth White (1936), working with Colebrook at Queen Charlotte's Hospital, showed that dust in single rooms used for patients with streptococcal puerperal fever contained the same streptococcus, and that sweeping and bed-making increased the numbers recoverable in plates exposed to the air. In one such room these proceedings were carried on for experimental purposes after the patient had left it, and the sweeper developed a throat infection due to the same type of streptococcus. It was also shown that streptococci in artificially infected dust will survive for 10 weeks, and that their mouse virulence is undiminished after 25 days. The infectivity of dust is also evident from the observations made by Brown and Allison (1937) in scarlet-fever wards. Diphtheria bacilli may also exist in floor dust in large numbers in the neighbourhood of infected patients; Crosbie and Wright (1941), who demonstrated this, also found that this organism can survive in stored dust, retaining its virulence, for as long as 102 days.

Cross-infection, by dust or otherwise, is particularly liable to occur in wards where there are many open wounds, and the war therefore concentrated attention on its mechanisms. The observations of Miles *et al.* (1940), Hare (1941), and Thomas (1941) have confirmed and extended our knowledge of dust-borne streptococcal infection, and the precautions necessary to prevent it are described in M.R.C. War Memorandum No. 6. The oiling of floors (van den Ende, Lusb, and Edward, 1940; Thomas, 1941) and of bed-clothes (van den Ende and Spooner, 1941; Thomas and van den Ende, 1941; van den Ende and Thomas, 1941) is now recognized as a valuable safeguard in diminishing the amount of atmospheric dust, and thus the chances of cross-infection by this means.

The original purpose of the work described in this paper was to determine how far dust is responsible for cross-infection in surgical wards, and how much cross-infection is to be ascribed to other causes. This aim was not reached, except in showing that, under the conditions existing in some of the wards studied, dust is so infective that, without the aid of any other vehicle, it could well have caused all the accidental infections observed. Owing to novel and unexpected features in the results obtained, a study was then made of the conditions governing the survival of haemolytic streptococci in dust.

### Methods

An ordinary sample of dust can easily be obtained by rubbing the dusty surface with a swab as used for throats or wounds: a large amount of dust, particularly of the fluffy variety, readily adheres to the cotton-wool. A few drops of sterile water were added to the tube containing such a swab, and a suspension of the dust was obtained by vigorously rotating the swab in this fluid. A loopful of this thick suspension was then sown on a 1 in 500,000 gentian-violet blood-agar plate (Garrod, 1942). The growth of almost all indifferent bacteria in dust, including all species of *Bacillus*, staphylococci, micrococci, *Sarcina*, diphtheroids, moulds, and yeasts, is inhibited on this medium, while *Str. pyogenes* grows freely and characteristically. So selective is the medium for this organism that almost pure cultures are sometimes obtained from an inoculum which on plain media would yield a confluent growth of bacteria classed in other circumstances as contaminants. That a thick suspension of what is really dirt should give either a nearly pure growth of a pathogen or an almost sterile plate is surprising, but it is a constant finding. *Vibrios* streptococci (not usually of a type found in the mouth) and occasionally coliforms are the only other organisms commonly encountered. All haemolytic streptococci were grouped, and disregarded if not found to be of Group A: in some cases, when their precise identity was of interest they were typed. I am greatly indebted for this typing to the kindness of Dr. S. D. Elliott and to Dr. Dora Colebrook, of the Research Laboratory for Streptococcal Infections, Medical Research Council. For some purposes, to be described later, dust was collected by other methods, and studied quantitatively.

### Distribution of Streptococci in Dust

Most of the observations hitherto made on dust-borne streptococcal infection have reference to floor dust. That this may be heavily contaminated with haemolytic streptococci, particularly under and around the bed of an infected patient, was amply confirmed in the present study. On one occasion a heavy throat carrier, whose condition was entirely unsuspected, was detected in the first instance by the discovery of very large numbers of haemolytic streptococci in the floor dust near her bed in an isolated corner of the ward. This was an 18-bed ward in which there had been a case of scarlet fever, while four other patients were known to be infected, either in a wound or in the throat. The floor was swabbed in the neighbourhood of each occupied bed, and while at least a few haemolytic streptococci were found in nearly every specimen (one exception being the floor beneath the bed previously occupied by the case of scarlet fever: this proved on inquiry to have been treated with dettol), the numbers were much greater in the neighbourhood of known infected cases and of the unsuspected carrier mentioned above.

This grossly infected ward was on the ground floor. Windows on the ground floor of this (E.M.S.) hospital are protected by brick blast walls built up to within 34 in. of the top of the

window at a distance of only 7 in. from it, thus shutting off the lower 4 ft. of the window completely. These wards are therefore very badly lighted, whereas wards on the first floor have no such protection and are well lit. Multiple specimens of floor dust were collected at various times from three ground-floor and three first-floor wards where cases of haemolytic streptococcal infection had occurred, usually in circumstances suggesting cross-infection, and there was a very marked difference between them in the frequency of positive findings (Table I):

TABLE I.—Number of Specimens of Floor Dust containing (+) and not containing (−) Haemolytic Streptococci

	−	+	% +
Ground floor .. ..	21	55	72
First floor .. ..	27	6	18

The two groups of wards were not strictly comparable, either in the circumstances prompting the investigation, which naturally varied, or in the type of case treated; but the difference between them was so evident as to suggest the overriding operation of one factor, and one possible factor appeared to be light.

Evidence capable of the same interpretation was being obtained at the same time in a different way. Dust was collected not only from the floors but from other surfaces on which it accumulated. The thickest dust (neglect of which is explained by shortage of domestic labour and lack of vacuum-cleaning facilities) was to be found on the black-out screens. Each window was obscured at night by lowering four hinged screens placed one above the other, and made of fibre board in a light wooden frame; by day these were hoisted and held by cords at an angle of about 70 degrees to the window. The sloping surface thus facing the ward, enclosed in a wooden frame over half an inch in depth, readily collected dust. Samples obtained from these screens and from parts of the windows themselves (e.g., upper surface of lower sash) form the first category in Table II. The second is a smaller category of sites intermediate in level between the window and the floor (skirtings and low shelves); the third consists of floor-dust specimens only. The figures refer to specimens from both ground-floor and first-floor wards.

TABLE II.—Number of Specimens of Dust containing (+) and not containing (−) Haemolytic Streptococci

Source	−	+	% +
Screens and windows	42	0	0
Skirtings, etc. .. ..	13	9	41
Floors .. ..	48	61	56

The difference in distribution here is clearly significant, and could be interpreted in the same way. Dust on or close to windows, and hence much more exposed to light than anything else in the ward, is, so far as these observations go, consistently free from haemolytic streptococci. It does not appear to differ in nature from floor dust, being composed mainly of blanket fluff, although it is lighter in colour owing to relative freedom from admixed dirt of various other kinds. It is possible, however, that a closer analysis of dust deposited at various levels might reveal unsuspected differences in composition.

In all the ground-floor and one only of the first-floor wards studied the floors were treated with spindle oil. This is known not to disinfect dust, but merely to prevent its diffusion. There is no apparent reason, on the other hand, why it should encourage the longer survival of streptococci, or otherwise so act as to complicate the interpretation of these findings.

#### Action of Light on Haemolytic Streptococci

Dust is an inconstant and difficult material to work with, and it seemed better to get further information about the action of daylight on streptococci by using some other medium. Buchbinder *et al.* (1942) obtained data on this subject by spraying organisms into the air, whence they settled on filter papers in Petri dishes; after exposure to various types of light these were cultivated. *Str. pyogenes* survived only 65 hours

in the dark under these conditions, which therefore seem unfavourable to the organism. Exposure to daylight (no sunlight) sterilized these preparations in about four hours. C. R. Smith (1942), studying the survival of tubercle bacilli after failing to detect them in dust from rooms occupied by sputum-positive cases, dried either culture suspensions or sputum on cover-slips, and exposed these in an unglazed north window. He found that the bacilli in these films were usually dead within four days, whereas in a drawer in the same room they survived for two or three months, and in a refrigerator for over six months. Survival was longer in films made of sputum. The use of natural material is clearly preferable, and Smith's method was adopted with modifications for the present purpose.

**Experiments with Films of Dried Pus.**—Pus containing haemolytic streptococci was diluted with sterile glass-distilled water (1 in 2,000 in the first experiment; 1 in 20 and 1 in 5 in later experiments), and a loopful of this dilution was allowed to dry. These slides, of which as many as 60 were made for each experiment, were placed film upwards in Petri dishes, and sets were kept in each of three or four situations: (1) the ledge immediately inside a first-floor laboratory window facing south; (2) the ledge inside a window on the opposite side of the same laboratory—i.e., facing north and never exposed to direct sunlight; (3) a dark cupboard in the same laboratory; (4) a refrigerator at about 4° C. Cultures were made, at lengthening intervals, by adding enough blood agar (about 4 c.cm.) at 46° C. to form an adequate layer over the slide. A confluent haemolytic growth from the area of the film was succeeded later, as the number of survivors fell, by diminishing numbers of discrete colonies and eventually by total sterility. The results of four such experiments are given in Table III.

TABLE III.—Survival of *Str. pyogenes* in Dried Films of Pus

Date of Start of Experiment	Dilution of Pus	Number of Days of Survival*			
		South Window	North Window	Cupboard	Refrigerator
Sept. 7, 1942 ..	1 in 2,000	<1	6-8	>18	
Nov. 11, " ..	1 in 20	3-4	7-11	31-45	
Nov. 13, " ..	1 in 5	10-13	13-17	75-92	>92
Mar. 6, 1943 ..	1 in 5	6-9	13-19	103-110	41-52

\* The first figure given is the day of the last positive culture, the second the day of the first negative: > means all films used before a negative was obtained.

The increasing concentrations of pus were used, as it was found that these thicker films were sterilized by exposure to ultra-violet light, and were thus suitable objects for testing the bactericidal action of other kinds of light. (For exposure of these films and other materials to measured doses of ultra-violet light I am indebted to Dr. L. D. Bailey and Miss G. H. of the physiotherapy department of this hospital.)

These observations tally with those of C. R. Smith. The streptococci died most rapidly in a position exposed to daylight, in spite of this having to traverse two layers of ordinary glass (the window and the Petri dish); survival was natural longest in the experiment begun in November. Diffuse daylight in the north window was also lethal within 13 days or less, whereas in a dark cupboard in the same room, and hence under identical conditions apart from light, survival was prolonged for many weeks. Survival was longest in the refrigerator in one of the two experiments employing this site; in the second, sterility after 52 days is unexplained, but may possibly have been due to the action of some noxious vapour.

#### Action of Light on Infected Dust in Vitro

Two attempts were made to assess the bactericidal action of natural light on haemolytic streptococci in dust. This was obtained by vacuum-cleaning from floors known to be infected and weighed in tubes, the contents of which were subsequently scattered in Petri dishes, and placed either on the north window ledge or in the cupboard already mentioned. Counts of colonies in pour-plates of gentian-violet blood agar from measured inoculum of volumetric suspensions showed little change in the cupboard dust and a fall of the order of 90% in the window dust within a few days; but duplicate counts

varied, owing evidently to lack of homogeneity in the material. This experiment was done in July. A much more elaborate repetition was begun in January, when heavily infected dust was obtained by passing a vacuum-cleaner over the bed-clothes of four patients known to have haemolytic streptococcal infections. This dust was filtered through gauze to remove coarse particles, yielding a dense fine grey powder, of which 10 mg. was kept in each of many tubes either in the dark or exposed to north daylight, and cultivated quantitatively from time to time. Neither in tubes nor in Petri dishes in which their contents were subsequently spread out as far as possible did this dust cease to yield haemolytic streptococci in culture until April 2, the experiment having been begun on Jan. 18. Winter conditions may have accounted partly for this long survival, but a more important reason was probably the nature of the material itself; ultra-violet light failed repeatedly under various conditions to kill more than a proportion of the streptococci in it, and it may be that dust in this artificially concentrated form is more protective to contained bacteria than the looser aggregations of natural dust.

The main interest of this experiment was the survival period in the dark. The original number of living haemolytic streptococci per gramme of dust was 204,000; succeeding counts were 176,000 on Jan. 25; 5,900 on March 19; 8,700 on April 2; 2,700 on May 4; 700 on June 4; and 300 on August 2, when the last available tube was cultivated. The three colonies in this last culture were all of Group A, and had sent to Dr. Elliott proved, as did a subculture from the plate of June 4, to be of Type 11. This type was responsible for the epidemic in progress in the ward when the dust was collected six and a half months earlier (195 days). This is the longest survival on record.

### Discussion

These imperfect observations are placed on record in order to draw attention to the possible importance of good natural illumination as a hygienic safeguard, and in the hope that they may lead to further study of this subject. Although good lighting is universally recognized as desirable, it has never, so far as I am aware, been insisted on as a prime necessity in wards for septic surgical cases. This study suggests that in such wards it has an important part to play, particularly if to special measures (such as the oiling of bed-clothes and vacuum dust extraction) are taken to prevent the atmospheric diffusion of dust. It has been shown that haemolytic streptococci naturally present in dust will survive for over six months in the dark. It was noticeable that dark corners on the floors of infected wards were always more liable to yield dust containing haemolytic streptococci than more open situations; one dark recess beneath a bookcase was repeatedly sampled, and never failed to yield them. Prolonged ward epidemics with long intervals between fresh cases are readily explicable in such conditions. It was also found that dust on or close to windows never contained haemolytic streptococci, whether exposed to direct sunlight or not. Whether this is an effect of light, or is partly or wholly explicable on other grounds, can only be settled by further observations.

The quantitative study of bacteria in natural dust *in vitro* is beset by difficulties, and it is not claimed that direct proof of the disinfectant action of light on this material has been obtained. Of the action of light on haemolytic streptococci in another natural medium there can be no question; dried films of pus are of the same nature as infected dry particles liberated from a wound dressing, and form an unexceptionable test object. These are sterilized within a few days by diffuse north daylight passing through two layers of glass, whereas in the dark the streptococci in them remain viable for weeks. My observations on this point differ from those of C. R. Smith, since no glass was interposed between his cover-slip films and the northern sky of California. Preoccupation with the ultra-violet part of the spectrum has led to a common belief that only direct sunlight is usefully bactericidal; it must now be recognized that ordinary diffuse daylight, even on a cloudy day and even in winter in England, can be lethal to bacteria, and that glass is no absolute bar to this effect. The conditions governing this type of light effect would evidently repay further investigation from several points of view.

### Summary

In wards where there are patients with haemolytic streptococcal infections dust may contain these organisms in large numbers, particularly near infected patients' beds.

Haemolytic streptococci were found to be most numerous in floor dust, and were absent from many specimens of dust in the same wards collected from sites on or close to the windows. They were more often found in dust from exceptionally dark wards than in comparable specimens from normally lit wards.

Haemolytic streptococci of Group A, Type 11, in naturally infected dust survived in small numbers in the dark at room temperature for 195 days.

Ordinary diffuse daylight is bactericidal to haemolytic streptococci. The interposition of glass does not prevent this effect, and it occurs even under winter conditions in England.

These facts suggest the possibility that good natural lighting may be a factor in preventing the atmospheric spread of infection in surgical wards and elsewhere.

I am indebted for valuable technical assistance in this work to Miss P. M. Waterworth. Her services and the equipment of the laboratory in which most of the work was done were made available by the generosity of "Bundles for Britain," which organization provided a fund under the control of Mr. Rainsford Mowlem for laboratory work in connexion with his surgical unit. I am also indebted to the medical superintendent of the hospital for permission to publish these findings, and to Mr. Mowlem and other members of the surgical staff for allowing me to refer to cases and conditions in their wards.

## A NOTE ON THE TRANSMISSIBILITY OF HAEMOLYTIC STREPTOCOCCAL INFECTION BY FLIES

BY

R. A. SHOOTER, M.B., B.Ch.

AND

PAMELA M. WATERWORTH

(From the Pathology Department of an E.M.S. Hospital)

During the investigations described in the preceding paper by Prof. L. P. Garrod, when explanations were being sought for cross-infections in surgical wards, attention was directed to the possibility that these might be conveyed by flies. Wounds and septic dressings attract flies, and in some circumstances cannot altogether be protected from them.

In Sept., 1942, when flies abounded in this hospital, it was decided to catch some and cultivate them. They were trapped actually in a Petri dish containing blood agar, one half of the plate being spread with three drops of 1 in 3,000 gentian violet, as recommended by Fleming, and simply incubated in the plates, their busy wanderings on the surface of the medium being relied on to inoculate it with whatever bacteria might be on their feet. After overnight incubation the flies were found dead.

The flies were caught in two surgical wards where there were cases with streptococcal infections; a control series was caught in the laboratory. Of 27 flies caught in these wards 3 gave sterile plates, 9 gave cultures containing haemolytic streptococci, three of which proved to be of Group A, while the remainder grew a variety of other organisms, including coagulase-positive staphylococci and coliform bacilli: 2 plates were overgrown with *Proteus*. Of cultures from 22 flies caught in the laboratory 5 were sterile, 2 overgrown with *Proteus*, and the remainder grew a variety of unidentified organisms; there were no haemolytic streptococci in any culture.

Two of the three Group A strains isolated from ward flies proved to be of Type 4. Since a close check was being kept on all wound and throat infections in these wards, all Group A streptococci being typed by the kind co-operation of Dr. S. D. Elliott, it is possible to trace a hypothetical relationship between a carrier condition in these flies and infections in the human population of the wards. Type 4 had been identified only once previously—in a sore throat in a nurse ten days before the infected flies were caught; it is possible that this nurse conveyed the infection to a wound in which it escaped recognition. During the following two months Type 4 was recovered from eight further persons, six having wound and two throat infections. All these cases occurred in one of the two wards studied, and it was in this ward that both of the Type-4-carrying flies had been caught. After this stage two patients—one admitted to each ward—were found to have a Type 4 wound infection on admission, and 15 further cases in the two wards during an ensuing period of three months from that time are therefore not necessarily traceable to the earlier cases.

These observations do not prove the transmission of haemolytic streptococcal infection by flies, but they strongly suggest its possibility. When infection spreads otherwise inexplicably from one part of a hospital to another this agency should perhaps be considered.

Acknowledgments are due, as in the preceding paper, to the fund by which this study of wound infections was supported, and to Mr. Rainsford Mowlem. The work was done under the direction of Prof. L. P. Garrod, to whom we offer our thanks.

## THE HALDANE HAEMOGLOBINOMETER

### 1. IRON, OXYGEN, AND THE BRITISH STANDARDS INSTITUTION COLOUR STANDARD

BY

R. G. MACFARLANE

AND

J. R. P. O'BRIEN

IN COLLABORATION WITH

C. G. DOUGLAS    E. M. JOPE    H. M. JOPE  
R. H. MOLE        B. AMOS    AND    P. QUELCH

(From the Department of Haematology, Radcliffe Infirmary, Oxford, and the Departments of Biochemistry and of Physiology, University of Oxford)

For more than 40 years the Haldane-Gowers haemoglobinometer has been in general use in this country, and for most clinical purposes it has been a satisfactory instrument. When, however, its results, changed by means of the traditional conversion factors into units of oxygen capacity and thence into grammes of haemoglobin, are compared with those of other methods in other countries, a curious discrepancy is apparent which has led to much confusion. Added to this, there is now a demand for a high degree of accuracy, resulting from the widespread adoption of the haemoglobin level as an index of nutrition and of haemoconcentration in shock. Judged by this more exacting requirement, it has become only too clear that the instrument as generally used may give dangerously inaccurate and variable results, and that a complete investigation of its efficiency is urgently needed.

The establishment by Donaldson, Harding, and Wright (*J. Path. Bact.*, 1943, 55, 205) of a permanent B.S.I. Haldane colour standard, together with a means for accurate comparison at the National Physical Laboratory, has, for the first time, provided the essential fixed point on which such an investigation must be based. We have taken advantage of this standard in certain observations, which, though they have no claim to the desired completeness, may serve to guide further work. The problem of haemoglobinometry has been solved to their own satisfaction by a succession of workers during the past 60 years, but it still exists in all its complexity. We have at least avoided this one pitfall, of supposing our results to be final.

The first step in the present investigation has been an attempt to determine the mean oxygen capacity and iron content of blood of a colour equal to 100% of the B.S.I. colour standard. This attempt, which has met with unexpected difficulties, is here briefly described. The variability of the results of haemoglobin estimation by the Haldane-Gowers method under different conditions and in the hands of a large number of trained observers will be dealt with in a second communication. Finally, the puzzling systematic discrepancy between the results of this method and those of others, bound up as it is with the history of the Haldane standard, will later be discussed in the form of a review of the literature.

### Method of Investigation

**Material.**—Blood was taken by venepuncture, a tourniquet being applied for the minimum time necessary to produce adequate venous distension and being released at the instant of puncture. The blood was heparinized, and within a few minutes of collection was divided into the required number of sub-samples, the vessel being shaken continuously to ensure even sampling.

The subjects were healthy adults (members of the hospital staff and medical students), 29 being males and 20 females. Unfortunately these were not evenly distributed in chronological order, most of the females being towards the end of the series—a fact that has complicated analysis of the results. The figures obtained in one other case, including an obviously erroneous iron estimation, have been omitted.

The following determinations were made on each blood sample and (except for iron determination) on the day of collection.

1. *Oxygen Capacity* (H. M. Jope).—This was estimated by the constant-volume van Slyke method, all measurements being made with carefully calibrated apparatus. Duplicate or triplicate estimations were made and the mean figure taken. In 20 blood specimens the CO capacity was also determined as a check on oxygen measurements. In addition 11 estimations of oxygen capacity have been made by Prof. C. G. Douglas, using the Haldane blood-gas apparatus, in parallel with the van Slyke estimations. The results of the two methods are in good proportional agreement, though the Haldane method gives results averaging 0.35 ml. % lower.

2. *Iron Determinations* (J. R. P. O'Brien and P. Quelch).—Haemoglobin iron was estimated by the Klumpp titanous chloride method, the results being the average of duplicate determinations. The method was standardized against pure iron wire, and all apparatus was carefully calibrated.

3. *Ultra-violet and Visible Absorption Spectra* (E. M. Jope).—A Hilger E3 medium quartz spectrograph and a Spekker photometer with ribbon filament lamp were used. The plates were matched on a photo-electric microphotometer. The results in the visible range were checked by two estimations made in parallel with the National Physical Laboratory spectrophotometer. To save space only the ultra-violet readings are quoted, and these have been expressed as a percentage of the B.S.I. standard on the basis of six determinations in parallel with the N.P.L. comparator.

4. *Haemoglobin Estimations* (B. Amos and R. G. Macfarlane).—The Haldane-Gowers haemoglobinometer was used. B.S.I. standards, diluting tubes, and pipettes were employed, and the necessary correction factors were applied. Each estimation was the mean of independent determinations by both observers, except for a period when one was not available. About halfway through the series both observers made many observations in parallel with colorimetric determinations by the National Physical Laboratory to eliminate personal errors, and this procedure was followed by rather higher readings being obtained from this point onwards. At the time of each estimation the observers were in ignorance of any other estimation on that blood sample—a matter of importance in view of the great susceptibility of this method to bias. In addition to the estimation of colour by the Haldane-Gowers method, six samples of blood were sent to the National Physical Laboratory for direct comparison with the colour standard by means of the special comparator. The figures so obtained were in

correlated with the other estimations which had been simultaneously carried out in Oxford. This procedure was designed as a check on the visual estimations of colour, which were considered to be most liable to error.

5. *Red Cell Counts* (B. Amos and R. G. Macfarlane).—Red cells were counted, using N.P.L. certified pipettes and counting-chambers. The recorded figures were the means of duplicate independent determinations by both observers.

6. *Packed Cell Volume*.—Duplicate determinations were made in N.P.L. certified haematocrit tubes, spun for 30 minutes at 3,000 revolutions a minute at a radius of 5½ in.

### Results

(Analysed by R. G. Macfarlane and R. H. Mole)

Space does not allow more than the means and coefficients of variation to be given, and these have been arranged in tabular form. The complete figures have been deposited with the Medical Research Council, and can be seen if desired.

TABLE I.—*Determinations (V = Coefficient of Variation)*

Estimation	(A) Series of 49		(B) 29 Males	(C) 20 Females	(D) 6 N.P.L. Samples
	Mean	V (%)	Mean	Mean	Mean
Haemoglobinometer reading (% B.S.I. standard)	101.40	9.00	106.60	92.95	103.40
Spectrophotometer reading (% B.S.I. standard)	102.50	9.38	109.30	93.20	(By N.P.L. comparator) 103.40
Red cells ( $10^6$ per c.mm.)	5.23	8.39	5.51	4.82	5.30
Packed cell volume (%)	44.80	7.61	47.03	41.55	44.60
Oxygen capacity (ml./100 ml.)	20.11	9.15	21.30	18.37	20.34
Iron content (mg./100 ml.)	50.40	9.98	53.96	45.24	49.83

The means and coefficients of variation are given for the 49 sets of six estimations in Column A. Then follow the means for males and females separately, and finally those of the six samples in which the haemoglobin was estimated by the N.P.L. comparator. From these six samples it was calculated that  $\text{HbO}_2$ ,  $E_{1\text{ cm}}^{1.000}$  ( $\lambda = 414 \text{ m}\mu$ ) 1.18 was equivalent to 100% of the B.S.I. standard, and the spectrophotometric readings are given as a percentage of this extinction coefficient.

TABLE II.—*The Mean Equivalent of 100% B.S.I. Standard, as determined by the Haldane-Gowers Haemoglobinometer (H), the Spectrophotometer (S), and, in Column 5, by the N.P.L. Comparator in Six Cases*

Estimation		Series of 49			Last 24			Six N.P.L. Cases
		All 49	29 Males	20 Females	All 24	11 Males	13 Females	
Oxygen capacity (ml. per 100 ml.)	H	19.89	19.97	19.78	19.60	19.48	19.71	19.70
	S	19.55	19.46	19.70	19.70	19.51	19.83	
Iron content (mg./100 ml.)	H	49.81	50.59	48.65	48.66	49.16	48.24	48.26
	S	48.97	49.29	48.50	48.90	49.25	48.67	
Red cells ( $10^6$ per c.mm.)	H	5.17	5.16	5.15	5.14	5.12	5.16	5.19
	S	5.09	5.03	5.18	5.17	5.11	5.22	
Packed cell volume (%)	H	44.37	44.11	44.73	44.60	44.80	44.30	44.72
	S	43.60	42.98	44.59	43.80	42.80	44.70	
Spectrophotometer reading	H	101.70	102.50	100.20	99.40	99.80	99.10	100.00

In this table the results have been expressed as the mean equivalents of 100% haemoglobin measured by the haemoglobinometer, the spectrophotometer (indicated by the letters H and S respectively in Column 2), and, in the last column, by the N.P.L. comparator on six samples. The values for the whole series and for males and females are given separately in Column 3. It will be seen that the haemoglobinometer ratios are consistently higher than those of the spectrophotometer, suggesting that the average readings of the haemoglobinometer were about 2% too low. Analysis of the series in chronological groups shows a reduction in this discrepancy

about half-way through the series when estimations in parallel with the N.P.L. were begun. The resulting change in the statistics affected the sexes unequally, since there were more females in the second half of the series than in the first. It is for this reason that the results for the last 24 samples have been given in Column 4, and here it will be seen that the two methods of estimation agree to about 1% or less.

Despite these variations, the following points are clear from Table II: (a) The B.S.I. standard is equivalent to about 19.7 ml. O<sub>2</sub> per 100 ml. and about 49 mg. of haemoglobin iron per 100 ml., instead of the expected 18.5 ml. O<sub>2</sub> per 100 ml. and 46.25 mg. Fe. (b) There seems to be a sex difference in the relations between iron, oxygen, and colour.

TABLE III.—*The Coefficients of Variation (V) of the Ratios of Haemoglobin as estimated by the Spectrophotometer (S) and Haemoglobinometer (H) to Oxygen, Iron, Red Cells, and Cell Volume Estimations, and of Iron to Oxygen*

Ratio:	O <sub>2</sub> /S	O <sub>2</sub> /H	Fe/S	Fe/H	O <sub>2</sub> /Fe	S/H	R.B.C./S	R.B.C./H	P.C.V./S	P.C.V./H
	S	H	S	H	S	H	S	H	S	H
Series of 49	3.12	4.27	2.42	4.04	3.46	3.48	4.66	4.00	3.46	3.68
Series of 24	1.81	3.68	2.47	3.92	2.85	2.95	5.31	4.28	3.58	3.36

Some idea of the correlation of two sets of variables is given by the coefficient of variation (V) of their ratios. Table III contains the values for V of the ratios given in Table II. A range of twice the coefficient of variation above and below the mean will probably be found in a series of 22 such ratios, and serves as a useful index of the "probable range" of variation. On the figures for the whole series, and taking  $\pm 2V$  as the probable range, in 22 blood samples with the same spectrophotometric reading two estimates of the oxygen capacity may differ by as much as 12%, or 17% if the haemoglobinometer is used instead of the spectrophotometer. It will be seen in this series that the best agreement is between iron estimation and the spectrophotometer, with a "probable range" of less than 10%.

The figures for the last 24 subjects show a considerable reduction in the variability of the ratios in which oxygen estimation takes part, particularly in that of oxygen to spectrophotometer in which the "probable range" has been reduced to about 7%. This improvement is presumably due to technical advance in the oxygen measurements. The other ratios show variable changes.

TABLE IV.—*Other Ratios: Colour Index; Mean Corpuscular Volume; Mean Corpuscular Oxygen and Iron; Oxygen and Iron Concentrations; Oxygen per gramme of Iron; Mean Corpuscular Haemoglobin; and Haemoglobin Concentrations*

Ratio	Series of 49		29 Males		20 Females	N.P.L. Samples
	Mean	V (%)	Mean	Mean	Mean	Mean
Hb/R.B.C. (C.I.)	0.967	4.00	0.969	0.965	0.97	0.97
P.C.V./R.B.C. (M.C.V.: c.m.)	85.8	4.03	85.33	86.46	84.52	84.52
O <sub>2</sub> /R.B.C. (M.C.O.: c.m.)	38.48	4.08	38.69	38.17	37.95	37.95
Fe/R.B.C. (M.C.F.: $\mu$ )	0.0964	4.87	0.095	0.0939	0.093	0.093
O <sub>2</sub> /P.C.V. (O <sub>2</sub> : ml. 100 ml.)	44.85	3.76	45.29	44.22	44.96	44.96
Fe/P.C.V. (Fe: mg. 100 ml.)	112.35	3.82	114.76	108.84	110.02	110.02
O <sub>2</sub> /Fe (O <sub>2</sub> : ml. g. Fe)	359.5	3.46	394.5	406.3	408.1	408.1
Hb/R.B.C. (M.C.Hb: $\mu$ )	28.7	4.03	28.76	28.64	28.67	28.67
Hb/P.C.V. (Hb: g. 100 ml.)	33.5	3.68	33.6	33.2	33.95	33.95

In this table the means of other ratios are given, usually in a form that is already familiar. The ratio of colour estimation to red cell count, for instance, is given as the ordinary "colour index"; packed cell volume to red cell count as the "mean corpuscular volume." The figures for mean corpuscular haemoglobin and haemoglobin concentration have been calculated from the haemoglobinometer readings by the use of Hufner's factor, and on the assumption that 100% colour is equivalent to our observed figure of 19.7 ml. oxygen per 100 ml. Such a conversion, included here for comparison with the previous findings in the literature, is arbitrary and gives a false impression of accuracy. The oxygen capacity per gramme of corpuscular iron is very near the theoretical figure, but again it is of interest to observe the sex difference.

### Discussion

A difficulty in attempting to define the British Standards Institution colour standard in any terms except those of colour is the fact that other measurable attributes of haemoglobin, such as iron content and oxygen capacity, are not, as determined by us, strictly proportional to the readings obtained with the Haldane haemoglobinometer and the spectrophotometer. Part of this lack of proportionality is, of course, due to instrumental and technical defects, and it is evident that as our series progressed some of these difficulties were overcome to an extent that materially lessened the variability. Nevertheless, even in the latter part of our series blood samples of the same extinction coefficient as measured by the spectrophotometer might show estimated oxygen capacities differing by 7% and iron contents differing by nearly 10%, while if the haemoglobinometer is used as a measure of haemoglobin these differences are increased to nearly 15% and 16% respectively.

A further part of this variability may be due to the presence of inactive haemoglobin and/or non-haemoglobin iron, the presence of which in larger amounts in men than in women might explain our observed sex difference. It ought to be pointed out, however, that this series was not planned to determine the extent of such sex differences, which were, in fact, not expected. In consequence our efforts to arrive at a satisfactory estimate of their statistical significance have proved fruitless, and the usual criteria, being in this series misleading, have been omitted. It is therefore difficult, if not impossible, to say how much of the observed variation between colour, oxygen capacity, and iron content was due to technical error, and how much to a genuine difference from one sample to another. Thus it is desirable to repeat the observations in a further series that has been carefully planned beforehand to make such an analysis possible.

It is quite clear that, in our hands, there is a large variability in haemoglobin estimation by the Haldane-Gowers haemoglobinometer. If a further series is attempted some other and more precise method for estimating colour must be employed—preferably the efficient comparator as used by the National Physical Laboratory.

Despite these variations there seems little doubt that the B.S.I. colour standard is equivalent to a greater mean haemoglobin, oxygen capacity, and iron content than was expected, though it is still conveniently close to the haemoglobin level associated with 5 million normal red cells per c.mm. This finding has an interesting bearing upon the supposed difference between English and American normal haemoglobin values.

also raises the questions why and when the standard changed from Haldane's original value, or whether in fact the Haldane standard has always been underestimated. These matters will be fully discussed in the third paper in this series.

### Summary and Conclusions

We have observed a lack of proportionality in the results of haemoglobin estimations by the Haldane-Gowers haemoglobinometer, the spectrophotometer, oxygen capacity, and iron determination on 49 blood samples.

Part of this variation is obviously due to technical error, and a further part seems to depend on a sex difference in the relative proportions of colour, iron content, and oxygen capacity of haemoglobin.

The British Standards Institution Haldane colour standard is apparently equivalent to  $19.7 \pm 0.2$  ml. oxygen capacity per 100 ml. of blood, and  $49 \pm 0.8$  mg. of iron per 100 ml. Because of the variation already mentioned, more exact figures cannot be given at present.

The Haldane-Gowers method for estimating haemoglobin has shown itself to be insufficiently exact in our hands for purposes of standardization, and, in any future attempt to define the B.S.I. standard, should be replaced by the N.P.L. comparator.

We are particularly grateful to Dr. R. Donaldson and Mr. H. O. W. Harding of the National Physical Laboratory for their willing and extensive co-operation. We wish to thank Dr. C. R. Harrington, Prof. R. A. Peters, and Dr. A. H. T. Robb-Smith for their criticism and advice, Dr. E. J. King for a sample of pure iron wire, and Dr. E. R. Holiday for placing the spectrographic equipment at our disposal. The expense of this investigation has been borne by the Medical Research Council.

## THE HAEMOGLOBIN EQUIVALENT OF THE B.S.I. HALDANE STANDARD

BY

E. J. KING, M.A., Ph.D.

*Reader in Pathological Chemistry in the University of London*

MARGARET GILCHRIST, M.Sc.

*Research Assistant at the British Postgraduate Medical School*

AND

AUDREY MATHESON, M.B., B.S.

*Medical Staff, Ministry of Supply*

The classical procedure of Haldane (1900) for estimating haemoglobin in the blood has been widely used in this country for nearly half a century, and most of the records in the medical literature of haemoglobin concentrations are in terms of the Haldane standard. By estimating the oxygen capacity of the blood of 12 healthy male persons Haldane arrived at an average figure of 18.5 ml. of  $O_2$  per 100 ml. of blood. This figure he took to be the oxygen equivalent of "normal" adult blood, and he defined his 100% haemoglobin standard in these terms.

The Haldane method consists in saturating a measured quantity of blood in water with carbon monoxide, and diluting the cherry-red colour so obtained until it matches a standard 1 in 100 dilution of 18.5 ml.  $O_2$  blood which has been similarly gassed with CO. For convenience the standard CO-Hb solution has usually been sealed up in small test-tubes of standard dimensions, in which it has appeared to remain unaltered in colour for surprisingly long periods of time, in some cases for many years. The quality of the glass undoubtedly has an effect on the keeping quality of the CO-Hb solution, and where inferior glass has been used, Haldane standards have been known to become unusable because of an obvious change in colour.

This and other shortcomings in the routine Haldane procedure led Clegg and King (1942) to adopt an alkaline haematin method of estimating haemoglobin, which, they showed, was readily adaptable to precise colorimetric measurement in either Duboscq or photo-electric instruments. For this method a haemoglobin concentration of 15.6 g. Hb, equivalent to 20.9 ml.  $O_2$  per 100 ml. of blood (Haden, 1922), was used as the standard 100% of normal, as this figure appeared from modern work (e.g., Peters and van Slyke, 1932; Wardlaw, 1941) to be a more probable average of normal adults than the earlier, and lower, Haldane figure.

Previously, all haemoglobin estimations in the Hammersmith Hospital had been made by the Haldane method, and it was anticipated that the determined percentage values would show a sudden drop on introducing the new method and the higher standard. The change encountered was much smaller than was expected. This led us to suspect that our Haldane standards represented a higher haemoglobin concentration than the 13.8 g. per 100 ml. which is the equivalent of 18.5 ml. of  $O_2$ . We have therefore calibrated our tubes of Haldane standard by reference to a number of bloods whose haemoglobin content has been assessed by accurate iron analyses (titanous chloride method of Delory, 1943) and comparisons with photometric haematin results. Our Haldane tubes have been compared by the National Physical Laboratory with the Haldane standard prepared by Donaldson, Harding, and Wright (1943). These authors have recently attempted to standardize the Haldane method and to define accurately the colour of the tubes of CO-Hb which are used as standards for the routine comparisons. As a result of our measurements we have determined that the colour of the British Standards Institution Haldane standard is in fact equal to that given by blood of 19.8 ml.  $O_2$  capacity (14.8 g. Hb) per 100 ml., and not of its stated strength of 18.5 ml.  $O_2$  or 13.8 g. haemoglobin.

### Experimental Methods

**Taking of Blood.**—(1) Blood was drawn by venepuncture without stasis and delivered into bottles containing potassium oxalate. It was mixed by gentle inversion before measurement. (2) Free-flowing blood from the lobe of the ear was collected

capillary pipettes. The lobe was carefully dried before pricking, and the first drop of blood was discarded.

**Pipetting.**—All pipettes were calibrated "to contain."

**Iron Analyses.**—Duplicate samples of 10 ml. of blood were iced and analysed for iron by the titanous chloride procedure described by Delory (1943). The  $TiCl_3$  was made up in freshly distilled water saturated with  $CO_2$ . The standard iron-alum solution was referred to B.D.H. "extra pure" iron wire (99.6% Fe).

**Alkaline Haematin Determinations.**—These were carried out according to Clegg and King (1942).

**Haldane Determinations.**—(1) "Direct" Method:—0.02 ml. of blood was delivered into 0.4% ammonia solution in an N.P.L.-calibrated dilution tube, gassed with pure  $CO_2$  and diluted to match the standard tube. (2) "Indirect" Method:—In one set of comparisons of the Haldane with the alkaline haematin procedure an attempt was made to eliminate sampling errors in the following manner. A single sample (0.2 ml.) of blood was diluted with 9.8 ml. of  $N/20\ NH_4$ , 1 ml. of this haemolysed solution, equivalent to 0.02 ml. blood, was used for the Haldane estimation; and 3 ml., plus 3 ml.  $N/5\ NaOH$ , for the alkaline haematin procedure. The 1-ml. Ostwald pipette was calibrated to "blow out" and a correction factor used. The same 3-ml. pipette was used for measuring both the haemolysed blood and the sodium hydroxide solution, and so no correction factor was necessary. Since the same blood solution was used for both methods the 0.2 ml. and 9.8 ml. measurements did not require to be strictly accurate.

**Measurement of Colour.**—The alkaline haematin test solutions were compared with standard haematin solutions in a Dubosq colorimeter using mercury green light, or in a King (1942) photo-electric colorimeter with a Chance green light filter. The  $CO-Hb$  solutions were matched by dropwise dilution of the test solutions to match the standard in a Hawksley comparator. The tubes were repeatedly shifted from left to right and right to left, following the "titration" procedure recommended by Haldane. The adding of diluting fluid and matching of colours were done by one operator, and the observations and recordings of the readings by a second. All comparisons were made in duplicate, in the first 20 comparisons by different observers, and the duplicates averaged.

**Determination of Haldane Equivalents.**—Each Haldane reading was subjected to the corrections furnished by the National Physical Laboratory for the standard, the dilution tube, and the pipette. (The N.P.L. calibration figures for tubes and pipettes agreed closely with the calibrations for the same instruments which we determined ourselves.) The 100% equivalent of iron, or of oxygen or haemoglobin, was calculated for each blood, and the average equivalent then taken for each series of bloods analysed.

### Results

**Comparison with Iron Analyses.**—Table I gives the results of the analyses of samples of bloods taken from 20 healthy adults, most of them Army medical officers.

**Comparison with Alkaline Haematin Values.**—These are expressed in terms of mg. of Fe or g. of haemoglobin per 100 ml. of blood. Three separate series of comparisons have been made—two in the London laboratory and one in the Provinces under field conditions using a portable photo-electric colorimeter for the alkaline haematin measurements. The figures are set out in Tables II, III, and IV.

### Discussion

The agreement between these results, both internally in each series of determinations and as between series, is good. The deviations from the average are well within the limits of error encountered in colorimetric methods. They are, indeed, surprisingly small in view of the uncertainties of matching to a dilution type of colorimeter (cf. Macfarlane, 1943), and it should be emphasized that it was possible to obtain reliable Haldane readings only by a rigid observance of Haldane's "titration" technique of colorimetric matching. The operator was ignorant of the reading of his matching in each case, since the value was observed and recorded by a second person. With proper precautions, therefore, it is possible to obtain

satisfactory agreement between the Haldane and alkaline haematin methods, and with iron analyses of the blood. The agreement appears to be satisfactory whether the comparisons are made on the bloods of healthy persons, hospital patients,

or industrial workers exposed to certain noxious chemicals. But it is improbable that the comparability would be as good with bloods containing a high proportion of methaemoglobin and sulphaemoglobin.

foreign object tends to produce strings of fibrin, which cause confusion in reading the results.) Set aside for five minutes, taking care to avoid drying up of the slide and soiling by dust. Rock the slide occasionally.

Results are read in from 5 to 10 minutes by the naked eye, and if necessary are confirmed by a hand-lens. The use of the low-power objective, as recommended by Steuer, is rarely necessary.

### Results

The tests were carried out on Egyptian labourers. Slides were taken in various camps under military control, were brought to the laboratory the same day, and were examined within the next 24 hours. In all, 640 persons were examined; 11 of these gave "slide-positive" results against OX 19, and 2 were positive to OX 2 in addition. These 13 were then followed up by a complete Weil-Felix reaction, using Dreyer's technique. The results are summarized in Table I.

TABLE I

Positive to OX 19	..	..	..	..	..	7*
Negative "	..	..	..	..	..	6

\* Of these 7 positives, 2 also showed agglutination in 1/50 against OX 2; and these two were the same persons who were slide-positive for OX 19 and OX 2.

The seven "slide- and Dreyer-positive" cases were further studied by carrying out a series of Weil-Felix tests at 4-day to 7-day intervals. The results obtained are shown in Table II.

TABLE II

Serial No.		1st Test	2nd Test	3rd Test	4th Test	Remarks
3	OX 2 OX 19	0 250	50 250	— —	— —	Had typhus a month before first test
4	OX 2 OX 19	50 50	50 125	50 500	— —	Not traceable afterwards
12	OX 2 OX 19	50 500	— —	— —	— —	Had typhus 3 weeks previously in hospital
19	OX 2 OX 19	0 500	— —	— —	— —	Not traceable: history not available
20	OX 2 OX 19	0 1,280	0 2,560	— —	— —	Hospital case: diagnosed typhus
21	OX 2 OX 19	0 250	0 1,800	— —	— —	Typhus with rash
22	OX 2 OX 19	0 250	0 250	0 1,250	0 1,250	Typhus with rash

Nos. 4 and 19, despite the history being unobtainable, should be considered typhus cases in view of the high titre. The others were definite typhus cases. It will thus be seen that all the clinical and Weil-Felix-positive typhus cases showed "slide agglutination" as well.

The results of the six slide-positive and Dreyer-negative cases (see Table I) are detailed in Table III.

TABLE III

Serial No.:	1	2	7	13*	15	17
OX 2 ..	0	0	0	0 0	0	25
OX 19 ..	0	0	0	0 0	50	50

\* Done twice, at five days' interval.

Except in two cases, there was no agglutination by Dreyer's method, and in neither of these was the titre high enough for diagnosis. These observations suggest that negative cases may occasionally give positive results, but this is not of much import. The fact that every clinical typhus case which was proved positive by the Weil-Felix reaction was spotted by the slide method is justification enough for urging the use of this simple technique as a preliminary to putting up a long series of tests by Dreyer's or Felix's method.

It was decided to try out a number of slide-negative cases by Dreyer's method, to see whether the zone phenomenon or some other factor would produce positive results in slide-negative cases. Thirty-three such sera were tested; the highest dilution put up was 1 in 250 and the lowest 1 in 25. Of these, 25 were completely negative; the remaining 8 gave agglutinations as shown in Table IV.

TABLE IV

Serial No.:	25	27	29	33	35	45	50	51
OX 2 ..	0	25	0	50	25	25	0	25
OX 19 ..	25	0	25	0	25	0	25	0

None of these titres has any diagnostic value.

It is reasonable to conclude from these results that a negative blood will not give a positive Dreyer test, certainly not of any diagnostic value. The low titres given in Table IV have no significance beyond perhaps the possibility that the individuals had developed some immunity as a result of subclinical infection, or had suffered from the disease some time previously.

### Comment

Having established that all positive cases can be detected by the slide method (of course to be confirmed by a complete agglutination test), and that the slide-negative cases will give a positive result by Dreyer's method, it is a reasonable assumption that a complete Weil-Felix test need not be done unless the slide test is positive. If this procedure is followed, the obvious advantages will be: (a) economy in material time; (b) avoidance of unnecessary bleeding of the patient; (c) easier dispatch of slides, as compared with that of blood or serum, to a laboratory situated at a distance from the hospital. Probably the test could be done on thick smears of blood, similar to those used for the detection of malaria parasites, and taken at the same time.

### Summary

A dry blood test for typhus has been tried out among Egyptian civilians.

It has been shown that all typhus cases give a slide-positive result, though a slide-positive result does not necessarily mean a positive case.

Control tests show that a negative slide will not give a positive Weil-Felix reaction.

The need for trying out this method on a more extensive scale is urged, and the advantages to be derived therefrom are discussed.

We thank Mr. A. C. Lahiri for his help in recording our results and with the typescript.

## Medical Memoranda

### Vaginal Ulceration and Vitamin C Deficiency

During the past six months several patients attending the gynaecological clinic at the Radcliffe Infirmary with acute ulceration of the vagina were given doses of 300 to 500 mg of ascorbic acid daily while investigations were proceeding to determine the aetiology of the ulceration. Healing occurred rapidly without further treatment. With this in mind it was decided in future to investigate the level of the blood ascorbic acid before starting treatment. The following cases are therefore of interest.

#### CASE I

A single woman aged 34, in apparently good health, complained of pain and discomfort on micturition and a continuous blood stained vaginal discharge for one month. There were two small areas of ulceration on the inner surfaces of the labia minora and an additional area on the vault of the vagina. They had a punched-out appearance of syphilitic ulcers and the acute tenderness of tuberculous ones. There was no surrounding induration, smears and cultures failed to reveal either treponema or gonococci, at the Wassermann reaction was negative. Biopsies showed no evidence of epithelioma and nothing suggestive of gonococcal, tuberculous or syphilitic infection. The urine was sterile and there was no glycosuria. Haemoglobin amounted to 98%, the red count was 4,900,000, and the leucocyte count 10,000. The blood ascorbic acid level was 0.04 mg./100 ml. The normal wartime level as found in a control series of apparently healthy persons was 0.4 mg./100 ml. (J. R. P. O'Brien—personal communication).

In view of these results the patient was questioned on her diet and it was found to be unusually lacking in green vegetables and fruit. The main meal of the day was taken in the canteen of a munition factory. Ascorbic acid mg. 150 t.d.s. was prescribed for three days, and mg. 100 t.d.s. for a further month. The ulceration had completely disappeared five days after starting treatment. The

seen no recurrence after six weeks. The blood ascorbic content rose to 0.84 mg./100 ml.

## CASE II

A healthy-looking married woman aged 38 complained of "acute in the front passage" a few days before menstruation and vere dysuria for four months. Owing to extreme pain and tenderness sexual intercourse for the previous four months had been impossible. On examination there was a condition of granulomatous ceration, involving the vaginal introitus, the suburethral angle, and the fourchette. There were also minute shallow ulcers within e vagina. Smears and cultures revealed no evidence of gonococcal treponema infection. The Wassermann reaction was negative. opsies showed benign non-specific ulceration. The blood picture is normal; the urine was sterile and sugar-free. The blood orbic content was 0.26 mg./100 ml. Ascorbic acid mg. 150 t.d.s. as prescribed for three days and mg. 100 t.d.s. for a further four eeks. All ulceration disappeared in six days and the blood ascorbic nent rose to 1.2 mg./100 ml. There has been no recurrence after e weeks.

These cases have reminded one of us (M. K. L.) of similar ginal conditions seen among West African natives and recog- zed as due to an avitaminosis. Varying degrees of avitaminosis produced varying degrees of vaginitis, ranging from a mild ritation with no pain to excoriation with painful ulceration. eatment with marmite, tomato juice, and citrus fruits was y successful.

The above cases were investigated and treated while under the care of J. A. Stallworthy, by whose kind permission we publish them. The orbic acid used was the preparation redoxon, supplied by Roche Products d.

## Anaphylactic Shock after Posterior Pituitary Extract Injection

he following unusual and alarming reaction to pituitary ract seems to justify publication.

## CASE HISTORY

An unmarried woman aged 32 was under my care two years ago r menorrhagia lasting from eight to ten days at each period. She proved after treatment with progestoral tablets and calcium injections. In Oct., 1942, she had another menstrual haemorrhage: it as so severe that she was unable to carry out her work, and came me for immediate help. I injected intravenously 10% calcium Sandoz and a mixed injection of 1 c.cm. of posterior lobe ituitary extract (gladutinrin Richter) plus 1 c.cm. of neofemargin ransmularly. Within a few minutes she complained of severe ins in the head, a feeling of apprehension, and blurred vision. e had an attack of coughing, and said that she could not breathe. e that the tongue felt swollen. At this stage I could actually e the eyelids, nose, and lips swelling, and the skin of the body as covered by an erythema and was hot to the touch. She also mplaind of retrosternal pains. The pulse was irregular and ecelerated up to 140. There followed pains in the epigastrium and ter in the lower abdomen. At this stage the nose became blocked, e eyes were running, and vomiting began. During all this time e patient was unable to speak, although she was not unconscious; ave her 2 c.cm. of nikethamide (coramine) hypodermically. A w minutes after the injection her condition improved; the pulse ame steadier and the rate decreased to 120 and later to 100, but eycardia persisted until the following day. After the nikethamide ection large quantities of very frothy fluid were vomited and eathing became easier. All the symptoms began to clear up: the welling of the face was greatly improved, and the exanthema faded adually. Itching of the feet, swollen eyelids, and head pains mained throughout the following day. The patient was able to ome five hours after the onset. One week later a slight irritant sh appeared on the side of the injection.

A noteworthy fact in her past history is that she had urticaria ter, eating fish during childhood. The picture resembled, to a rtain extent, anaphylactic shock after serum injection.

## COMMENTARY

During 17 years' practice I have given several thousand injections of pituitary extract and ergotin, either alone or mixed, and have never seen a similar reaction; moreover, on discussing is with colleagues I have found no one else who has seen case like it. The question arises whether this reaction was ooked by the pituitary extract or by the neofemargin, which ntains ergometrine. Chassar Moir (1936) reported a few ses of unusual reaction to ergometrine, and considers the ossibility of a rare idiosyncrasy to that drug, but his cases owed a different appearance. Their faces were grey and overed with sweat; there was no sign of glottis or pharynx edema, no rash or itching. It seems to me that the case I ve described was due to the presence in the pituitary extract some traces of protein or to hypersensitivity to pituitary ract produced by some other unknown substance. The

picture of pituitary shock which sometimes occurs in patients is clinically characterized by pallor, increased pulse rate and fall of blood pressure, headache, and occasionally abdominal pains, nausea, and vomiting. These symptoms are due to capillary vasoconstriction and coronary spasms, and they differ from those I have described here.

I found very little explanation in the literature. Simon and Ryder (1936) reported five cases of hypersensitivity to pituitary extract in patients with a family or personal history of allergy, but all had been sensitized by previous pituitary injections, whereas my patient had never before had an injection of pituitary extract. These authors made skin tests with different extracts, and showed that the sensitivity is not limited to one particular brand of extract and is not due to vasopressor or oxytocic factors but to some constituent of the gland. Sullivan and Heffernan (1942) describe three different varieties of toxic reactions following the use of pituitary extract: (1) pituitary shock; (2) pituitary reaction resembling true anaphylactic shock; (3) more rare tetanic convulsions with either a rise or a fall in blood pressure.

Although conclusions cannot be drawn from one case, it seems advisable to avoid pituitary extract injections in cases with a history of allergy and to give only small doses if a patient has previously had the extract, until it is certain that there is no hypersensitivity.

London, W 1 E. SCHLEYER, M.D. Vienna, L.R.C.P. & S.E.D.

## A Case of Cavernous Sinus Thrombosis

The following case is of interest as an addition to the number of recorded recoveries.

## CASE HISTORY

A boy aged 14 struck the region of his left eyebrow on a door-handle. On account of soreness of the part he attended hospital two days later, but no abnormal signs were then evident except for a slight skin abrasion. The following day the eye began to become prominent and the temperature mounted to 103°, and on admission that evening there was gross left proptosis with chemosis as of an orbital cellulitis. The next evening the other eye became equally protruded, and the day after that the whole face was grossly engorged. By that time he was vomiting, was doubly incontinent, and had become semi-comatose. This state lasted a week, during which time the fever remained around 103°; then gradual recovery ensued, with decongestion of the face and a return to continence and consciousness. On the 5th to 8th days after admission there were attacks of tremors affecting all muscles of the face, and to a lesser extent the arm, on one or sometimes both sides; these lasted a few minutes and occurred several times a day. No fundus changes were evident except slight engorgement of the retinal veins and doubtful blurring of the optic disk margins, especially on the left side (the side first affected). On his return to consciousness a residual left facial palsy was observed, clearing in about a fortnight. There were also stiffness of the right leg with extensor plantar reflex, and left external rectus paresis, which disappeared in a few days. His convalescence was delayed by a mild basal pneumonia and a small subcutaneous orbital abscess. Vision was 6/5 right and left.

Treatment included administration of sulphapyridine, which could only be given intramuscularly after the second day, and later sulphadiazine by mouth—32 g. in the first week (1 g. 4-hourly for 2 days, then 6-hourly for 5 days) and 21 g. in the second week (1 g. 3-hourly). Four pints of glucose-saline 5% drip transfusions were necessary while he was incontinent, vomiting, and unable to take fluids by mouth.

## COMMENTARY

Cavernous sinus thrombosis has been regarded as a uniformly fatal disease: in 1936 a 100% mortality was recorded in a survey of literature by Grove. With the advent of the sulphonamides, however, some 12 cures have been effected. In at least 3 cases, in conjunction with sulphathiazole, heparin has been used with success for the prevention of any extension of the clotting; in addition staphylococcal antitoxin is recommended even where (as in this case) the blood culture is negative and no adjacent furuncles can be incriminated, since before the sulphathiazole takes effect there is a lag period in which the antitoxic agent is of great value.

In this case the infection presumably reached the orbit from a nasal sinus through a fracture of the intervening bone, although this could not be shown subsequently on an x-ray film. The meningeal irritation producing localized tremors, and the residual palsies, are a frequent accompaniment, and confirm the diagnosis. Retinal changes have rarely been severe in those cases which have recovered.

I am indebted to Mr. P. G. Doyne and Dr. S. P. Meadows for permission to record this case.

## Reviews

### HUMAN BIOLOGY: THE PECKHAM EXPERIMENT

*The Peckham Experiment: A Study of the Living Structure of Society.* By Innes H. Pearse, M.D., and Lucy H. Crocker, B.Sc. (Pp. 333. 12s. 6d. net.) London: George Allen and Unwin, Ltd. 1943.

The Pioneer Health Centre at Peckham took shape in 1926, when a small house was occupied in South London with a view to offering to the families of the neighbourhood a health service built up on the pattern of a family club, with a periodical health overhaul for all its members, and with various services for infants, children, and parents alike. In 1935 it entered into possession of a modern building, specially constructed and equipped as a "laboratory for the study of human biology." The amenities of the Centre were intended for families within walking distance, so that it was a local enterprise, but with the literature which it is accumulating Peckham may well come to stand not for a suburban habitation but for an idea, and a very fertile one at that. *The Peckham Experiment*, the writing of which has been made possible by a grant from the Halley Stewart Trust, is the third of four books on the subject. The first two—*The Case for Action* and *Biologists in Search of Material*—appeared in 1931 and 1938, and the fourth, to be entitled *Science, Sanity, and Synthesis*, is to follow. The present work, by two women. Dr. Innes Pearse and Miss Lucy Crocker, both of whom have had social experience in the East End of London, is not a description of the Peckham Centre, with some general conclusions to be drawn from its work; rather it is an essay on human biology with illustrations derived from Peckham. It deals wisely and penetratingly with the subject of the family, which is the unit of the Centre's operations, and it discusses the phenomena of courtship and mating, the bringing up of children, and social poverty and sufficiency in a way which is scientific and original, but never losing sight of the human subject in the mass of biological material. Perhaps that is because the authors are not writing out of the void, as it were, but on the solid basis of the work at the Centre, with its manifold activities and its human interest.

Falling in love is a theme which has suffered alike at the hands of romancers and cynics; but these trained biologists manage to deal with it understandingly and sympathetically. The growing pains of adolescence can hardly ever have been better described than in Chapter XI. Another fundamental idea of the Centre, which is reflected in these pages, is the importance of the father, that neglected shadowy figure in all maternity and child welfare organization. The Centre introduces him into the parental consultations; his presence there is made to appear a matter of easy and natural routine, so that instead of being a shy and anxious spectator of his wife's pregnancy his attitude is likely to become one of intelligent interest and active partnership, without any sneaking regret for what has happened or any dread of what lies ahead. Peckham affirms that pregnancy is a condition in which Nature has destined woman to be at her best, that there is no basis for the relegation of the pregnant woman to the position of "patient" to which modern civilization has condemned her, but it adds that in all parenthood from its very beginning the role of the father as well as of the mother as a specialist in the nurture of their child is of the utmost importance to the family as a functional unity. Peckham deserved a book, but this volume deserves a multiplication of Peckhams.

### BRONCHIECTASIS

*Bronchiectasis: Pathogenesis, Pathology and Treatment.* By James R. Lisa M.D., and Milton B. Rosenblatt, B.S., M.D. Oxford Medical Publications. (Pp. 190; illustrated. 21s.) London: Oxford University Press. 1943.

This book, by two American authors, is badly conceived, being either too long or too short. It is written to review current ideas on the pathology and pathogenesis of bronchiectasis, describe the pathological findings in 110 cases studied by the authors, and elaborate their conclusions as to its cause. The book opens with a chapter on the anatomy of the bronchi, and includes others on the symptoms and treatment of bronchiectasis. These occupy one-third of the contents, and

could well have been either omitted or amplified. They contain little that is unfamiliar to the reader who will be interested by the main subject in the book, but are not comprehensive enough for a textbook on bronchiectasis.

The authors examined the lungs of all cases that came to necropsy at the City Hospital, Welfare Island, in 1939; the (110) showing evidence of bronchiectasis were cut serially at the sections were stained by various methods. A clear description of the findings, with many photomicrographs, is given. The authors found that a similar infective process existed whatever the associated condition of the lungs. They then describe the theory of the pathological sequence of events, and conclude that the disease is always basically due to an infective atelectasis and other suggested causes being either coincident with or adjuvant to infection. This theory is attractively argued, but the objections to it, though mentioned, are not completely met. A useful list of references to the authors quoted is given, but it is confined to workers in either Britain or America.

The book can be recommended to those who are interested in the pathogenesis of bronchiectasis as a valuable contribution to its study.

### BRITISH MEDICINE

*Medicine in Britain.* By Hugh Clegg, British Life and Thought, No. 46, illustrated. 1s.) Published for the British Council by Longmans Green and Co.

When Mr. Seward, fishing for an acknowledgment that John had himself written Dodd's *The Convict's Address to Unhappy Brethren*, said that it had more force of mind than any of Dodd's earlier works, the doctor sharply rejoined "Depend upon it, Sir, when a man knows he is to be hanged in a fortnight it concentrates his mind wonderfully." To require to tell in fifty pages the whole story of *Medicine in Britain* and to make clear to a foreigner the evolution and prospects of our heterogeneous system may not be so great a prospect as a journey to Tyburn, but could not be performed tolerably without great concentration of mind. Dr. Clegg has performed it admirably. In his historical sketch he makes individualism and resentment of central control so clear that a foreigner will not be puzzled by the existence in a small island of 24 licensing authorities—though he may still be perplexed by the social custom which requires a surgeon to eschew the prefix "Dr.," however ample his academic claim to the title.

In describing present conditions and aspirations Dr. Clegg cannot avoid controversial topics, and writes dispassionately without being dull. The following passage seems to be admirable: "In view of the intimate nature of the patient-doctor relationship, the medical profession believes that the patient must have the right to choose and to change his her doctor, and that the doctor may have the right to refuse to continue looking after a certain patient. In this, it is a freedom to change rather than to choose which is important. To a critical foreigner—conscious of the notes in others' ears—the battle-cry 'Free choice' seems an example of 'British hypocrisy.' Whoever, he may say, ever had or could have free choice of doctor; even Marcus Aurelius could not, or not, enforce his free choice of Galen? We know what we mean but the last sentence in the passage quoted is required by a foreigner. Whether there might not be freedom to choose under many systems is another story. Dr. Clegg is not a propagandist, and criticizes our system. Sometimes he is a little harsh. He writes: 'On the whole it cannot be said that the Ministry of Health has been as progressive as most progressive of the local health authorities—such, for example, as the Middlesex County Council and the London County Council. Its activities as a forward-looking health authority have suffered as a result of fluctuations in general policy—a disadvantage suffered by all centralized authorities subject to political influence and change. Nevertheless during the present war the Ministry of Health has taken a very much more active part in promoting the health of the people than it has done in the past.' Until the present war the Ministry of Health had not the power to be progressive in the way that a local authority could be progressive, precisely because it is not a local authority. We think nearly all foreigners and good many Englishmen could learn a great deal from this excellent booklet.

## DISORDERS OF THE MIND

*The Nature and Treatment of Mental Disorders.* By Dom Thomas Verner Moore, O.S.B., Ph.D., M.D. Foreword by Edward A. Strecker, M.D. (pp. 312, 54.00.) New York: Crane and Seratone, 1943.

This study comes from the Catholic University of America, and naturally shows signs of the special attitude of mind, both of psychiatrists and of patients, which is inseparable from the profession of the Roman Catholic religion. In the author's view mental disorder is essentially a psychological problem, and in his introductory chapters he is inclined to deny any relationship with the anatomy and physiology of the central nervous system, though later he refers to physiological changes in the hypothalamic area causing emotional expression and even changes of mood and suggests that such physiological changes may explain the intractability of much psychotic emotion. It is shown that Kraepelin's contention that definite clinical syndromes of mental disease may be described can be mathematically confirmed.

The author next considers the factors on which psychoses depend, and the theories of Freud, Jung, Adler, and Alexander are briefly described and examined. He then shows how emotional states can start and maintain organic changes through the autonomic system. He instances isolated emotional shocks apparently determining psychotic breakdown but considers that there is always a pre-existing disposition and points out that there is usually an interval of "brooding" between the emotional incident and the onset of the psychosis.

He considers that chronic emotional stresses may determine mental disorders, but does not believe that direct sexual factors such as celibacy, continence, or masturbation themselves contribute. He takes the "phobia" as a useful field of study. He points out that these are not always sexually determined. Child fears do not always develop into phobias, and may be dispensed by wise home handling. Even phobias may spontaneously disappear in fortunate circumstances, but examples are given in which phobias are retained because they are consciously or unconsciously useful to the patient.

Under the section on treatment the successful analytic treatment of a case is described, and the success of simple free association is recorded in another case. The author illustrates the usefulness of psychotherapy in psychosomatic diseases, and points out how religion (Catholicism) and simple talks may be of great service, quoting as examples cases of marital disharmony and the problems of the unwanted and over-protected child. He refers to the usefulness of play therapy, reorganization of the family and school relationship, drawing attention to emotional retardation as opposed to awkwardness. He thinks that "bibliotherapy"—the choice of appropriate books for the patient to read—may be of great use. He illustrates how the rapid elimination of hysterical symptoms in children by counter-suggestion may clear up the whole psychoneurotic situation. Since emotional states can be induced by physiological changes in the hypothalamus, he maintains that drug treatment may well be useful, and refers specially to convulsive therapy by insulin, metrazol, and electrical methods, to hyperpyrexia and the administration of adrenal cortex and pituitary hormones. There is an appendix on the classification and definition of the clinical entities of psychiatry.

This work is well illustrated by case records; but contains nothing very new or original, and the up-to-date British psychiatrist will find the book interesting reading but will probably conclude that he has heard it all before.

## Notes on Books

J. H. WOODGER's *Elementary Morphology and Physiology for Medical Students*, which he aptly describes as "a guide for the first year, and a stepping-stone to the second," has reached a third edition (Oxford University Press; 15s.). This issue is distinguished on its predecessors by a well-illustrated chapter entitled "A Digression on Insects." Taking the American cockroach (*Periplaneta americana*) as exemplifying the principal features of a typical insect, describes this one example in sufficient detail to enable a student grasp the essential features of the structure and function of the various parts and organs of the order Insecta as a whole, and also

to follow descriptions of those of medical importance, the more important of which are briefly noted at the end of the chapter. With full appreciation of the difficulties imposed by limitation of space in writing an elementary textbook, one would have liked to see greater stress laid upon the essential part played by response to environmental changes in both plants and animals, and to the undeniable evidences of the inheritance of modifications of structure and function which have been produced by climatic, parasitic, and other changes in environment causing either evolution or regression. In considering modern developments of the Mendelian theory, some of which rest upon assumption, there seems to be a tendency to place undue importance on the levelling influence of amphimixis on chance variations, while the causes concerned in the production of these variations are apt to be lost sight of. Bearing in mind the importance of a sound knowledge of heredity for the medical practitioner, we think that the value of the bibliography at the end of the book would be greatly increased if there were included in it—along with references to the standard works of Darwin, Wallace, and others—the names of a few special short works which give the essential points of the main theories in a small compass.

## Preparations and Appliances

## A PERITONEOSCOPE

Mr. GERALD OVENS, F.R.C.S., writes from St. Bernard's Hospital, Southall, Middlesex:

The value of peritoneoscopy as an additional method of diagnosis in obscure abdominal lesions is being increasingly recognized; but two factors—expense and the difficulties of obtaining a suitable instrument at the present time—have largely prevented its more widespread use in this country.

I am indebted to Mr. Schranz of the Genito-Urinary Manufacturing Company for designing for me a simpler and cheaper instrument which, while not intended to replace the Ruddock peritoneoscope, has in practice been found of great value in differential diagnosis and in assessing the operability of abdominal tumours.

The expense of all these endoscopic instruments lies chiefly in the optical portion. This peritoneoscope has been designed for use with the standard telescope supplied in H.M. Government cystoscopic sets, which thus becomes interchangeable, but it can readily be built to fit any telescope provided. It consists of: (1) A cannula with air inlet cock and trocar (Fig. 1). (2) A sheath similar to that of an examination cystoscope carrying a lamp at the distal end, and the usual connexion adjacent to the valve chamber (Fig. 2). (3) A standard 90° telescope (Fig. 3).

Fig. 1

Fig. 2

Fig. 3

The diameter of the sheath is slightly smaller than the lumen of the cannula, leaving sufficient space for the passage of air. It is held in position by means of an adapter which can be locked to the cannula.

In using the instrument a pneumoperitoneum is first induced under local or general anaesthesia by means of an ordinary artificial pneumothorax induction needle. The trocar and cannula are then inserted and the telescope removed. The adapter is locked to the cannula and the telescope and sheath inserted through it. A slight tightening of the locking device secures an air-tight joint. Bellows are now attached to the lateral connexion on the cannula, which is provided with a tap so that when sufficient air distension has been obtained the bellows may be discarded.

The instrument may be obtained from the Genito-Urinary Manufacturing Company, 284, Devonshire Street, W.1.

## TUBERCULOSIS IN WALES

The latest annual report of the King Edward VII Welsh National Memorial Association includes an address which its president, Lord Davies, delivered at the annual meeting.

Lord Davies referred in particular to the two important measures which have been taken in combating tuberculosis—namely, mass miniature radiography and the payment of maintenance allowances to dependants of persons suffering from pulmonary disease. Public opinion in Wales, he said, had been ready to welcome and utilize mass radiography for some time past. In 1941 the association approved an experimental scheme for the provision of mass radiography apparatus suitable for the conditions prevailing in Wales, including a vehicle for transporting it around the country. The initial cost of £5,500 was sanctioned by the Welsh Board of Health, but there had been some delay in securing the apparatus, and at the time he spoke its delivery in this country was still awaited. Meanwhile, the Ministry's set, although much less mobile than that which the association designed and ordered for itself, would be most useful in large centres of population in Wales. With regard to financial grants, Lord Davies drew attention to a leaflet (amplifying the model leaflet suggested by the Ministry) issued by the Flintshire County Council, pointing out that allowances were made under the Government scheme for pulmonary tuberculosis only, but that the county council provided additionally for all types of tuberculosis, and that the Government allowances would be operated as part of the county council's existing after-care scheme for pulmonary and non-pulmonary tuberculosis. He added that in Flintshire, out of 67 applications for assistance considered at a recent meeting of the Care Committee, 49 were found to be outside the Government proposals, thus showing the need for a fully effective care scheme in every area in Wales. Lord Davies referred to the National Memorial Association's plans for the future, temporarily postponed by reason of the war, which include the provision of additional beds at the tuberculosis hospitals, a new and enlarged research laboratory at Cardiff, modern clinics in all the large centres of population, an adequate and uniform health visiting service throughout the Principality, an extension of health education, and the establishment of a village settlement or settlements for the training of patients in suitable occupations. The treatment of chronic pulmonary disease as it affects coal-miners in Wales is at present under consideration.

## Reports of Societies

## HAND INJURIES

At a meeting of the Association of Industrial Medical Officers in January the chairman, Dr. J. C. BRIDGE, presiding, Mr. R. M. HANDFIELD-JONES and Dr. P. H. JAYES opened a discussion on injuries, infections, and burns of the hand.

Mr. HANDFIELD-JONES said that the commonest minor injuries affected the distal segment of the finger. As fibrous trabeculae divided the pulp of the finger into a series of narrow compartments, operation for drainage of a pulp infection, to be effective, must open all the infected compartments at once. A pure pulp infection must be differentiated from lymphangitis; in the latter incision was contraindicated, and each patient should be regarded as a potential fulminating case and be put to bed with the arm raised to 45 degrees, local antiphlogistine and early massive doses of sulphanilamide being given. Tendon-sheath infections were serious in that complete return of function could never be guaranteed. Early incision was essential. Infection of the palmar spaces caused swelling and tenderness of the palm. The swelling when the middle palmar space was involved was not so noticeable as the "ballooning" in the case of the infection of the thenar space. These infections were usually caused by spread from others, and were rarely direct. Patients with injuries of the hand, especially compound fractures, should be treated as in-patients. The wounds, having been cleaned, should be filled with sulphanilamide powder, loosely stitched, and subjected to some form of traction. Early active movements were essential. It was much easier to avoid a stiff joint than to loosen a joint which had been allowed to become stiff. Position in treatment was often important. The oedema could be minimized by raising the arm on a wooden frame; to have it lying on a pillow was not enough. If a stiff

joint appeared inevitable the hand should be kept in the proper position for function, as stiffness in an unsuitable position gave an unsightly and useless hand. By suitable splinting support and the intelligent use of elastic traction deformities and stiffness of joints might be avoided.

Dr. P. H. JAYES said that treatment of burns of the hands depended on the facilities available and on the nature of the case. As a general rule burns of first or second degree were not much trouble, and whatever treatment was adopted full function usually resulted. Third-degree burns of the hands raised many problems of treatment. Skin grafting was often necessary to attain a full functional result. Coagulants did not as a rule give the best results on account of constriction of the fingers and consequent interference with blood supply, caused not only by the coagulum but by the oedema so commonly present beneath it. The coagulum was often so stiff that it splinted the finger for many weeks; the stiffness was difficult to overcome at a later stage. The saline bath was used for all severe burn cases. Efforts were made to prepare denuded areas for skin grafting at an early stage. Dressings were soaked off in the bath and the parts were exercised by active movements at the same time. After drying, the burned area was powdered with sulphanilamide and covered with tulle gras, with a moist saline compress over it. Most cases were skin-grafted by the end of three weeks. It was important to be sure that the denuded area was free from haemolytic streptococci. If the swab was positive grafting was postponed and efforts made to sterilize the skin by the local use of sulphanilamide and propamidine. Dr. Jayes stressed the importance of keeping the hand moving while waiting for grafting. If joints had been opened and stiffness seemed almost inevitable, the joint should be kept in the position of election for optimum function. Cases seen at a late stage with contractures due to tight scars could often be improved by dissecting away the scar and replacing it by Thiersch grafts. In some cases a full-thickness skin graft from the abdomen was necessary. First-aid treatment for burns should be as simple as possible, and in many cases covering with a sterilized dressing was sufficient. At hospital the area was carefully cleaned up under aseptic conditions; CTAB detergent solution was used for this. Blisters and loose skin were trimmed away, and the whole of the area was covered with sulphanilamide powder, tulle gras, and saline compress.

Dr. D. W. Winnicott recently addressed a meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health on the significance of psychology in infant welfare work. He stressed the mother's intuitive understanding of her child and her appreciation of the importance of the infant's feelings to the infant, the intensity of those feelings, and the reality of infant distress. He suggested that if many things which the ordinary good mother knew intuitively were accepted by doctors there would be no interference with any mother-infant relationship except where absolutely essential, and much unnecessary harm would be prevented.

The Colonial Office announces that a new campaign is to be launched in the South-West Pacific against the *anopheles* mosquito, which, if introduced to the British islands at present free from infection, could cause as many casualties as combat warfare. This scheme is to be financed under the Colonial Development and Welfare Act, 1940, and an initial grant of £65,000 to cover three years has been made for the purpose. The *anopheles*, and consequently malaria, have hitherto been unknown in the territories of Fiji, Tonga, the Cook Islands, the Loyalty Islands, New Caledonia, the Gilbert and Ellice Islands, and Samoa. In the islands to the west of Fiji, on the other hand, malaria is widely distributed. In peacetime, when there was little shipping traffic between the islands and air services were unknown, the danger of the spread of infection was small, and the routine malaria control was considered sufficient. But since the outbreak of war, the establishment of large garrisons and the increase of air and sea traffic between the islands have greatly increased the danger of introducing malaria to the "clean" islands. A start is to be made with entomological surveys near shores and ports, and reconnaissance surveys of all potential breeding-grounds. Normal antimosquito work will be intensified and danger-places will be cleared, drained, and oiled. At the same time an engineer will prepare a scheme for mosquito control on a long-term basis.

## DAYLIGHT AND DUST

It has been known since Kirstein's<sup>1</sup> extensive experiments in 1902 that certain pathogenic bacteria, particularly members of the respiratory group (for example, tubercle and diphtheria bacilli, streptococcus, and pneumococcus), may, after natural drying, remain alive for many days or weeks. However, Flugge's<sup>2</sup> earlier work showing the limited range of infective droplets expelled by consumptive patients during coughing and talking, together with the difficulty experienced in infecting guinea-pigs with dried tuberculous sputum, led to a general acceptance of the dictum that the spread of respiratory infections occurred predominantly by the spray or droplet method, which requires close contact between infective and susceptible persons. In recent years there has been a renewal of interest in the possibility of dust-borne infection, but, in spite of much laboratory evidence that the dust in scarlet fever, diphtheria, and ear-nose-and-throat wards may contain many millions of haemolytic streptococci or diphtheria bacilli, clinicians have been unwilling to believe that dried "emasculated" bacteria are capable of initiating infection. In actual fact Buchbinder and his colleagues<sup>3</sup> have shown that naturally dried streptococci do not suffer any loss of virulence or attenuation in any other of their activities. Absolute proof of the infectivity of dust is not easily obtainable, but there is now a considerable body of circumstantial evidence in support of this view. Thus White,<sup>4</sup> after sweeping out a cubicle vacated three days earlier by a puerperal patient infected with a particular serological type of haemolytic streptococcus, herself developed a tonsillitis due to a streptococcus of the same serological type. Cruickshank and Godber<sup>5</sup> showed in two small outbreaks of puerperal sepsis that the most likely reservoir of the infecting streptococcus was the air or dust of the wards, and that secondary streptococcal infection in a diphtheria ward was most probably dust-borne. On the assumption that infected dust is an important vehicle for the spread of respiratory infection, and perhaps also for hospital infection of open wounds, van den Ende and his co-workers<sup>6</sup> have devised methods for controlling the dissemination of dust in wards by oiling of floors and bed-linen, which prevents the dust being raised into the air during sweeping and bed-making. Treatment of floors with a strong antiseptic solution has been recommended by Crosbie and Wright<sup>7</sup> for the same purpose, and in our present issue Garrod brings forward

evidence that daylight may be of material value in reducing the risk of dust-borne infection.

The bactericidal action of the ultra-violet rays from sunlight or from special lamps is well known, and has lately been used in American hospitals and schools to control the spread of respiratory infections, and in surgical theatres to prevent skin sepsis after prolonged operations. Direct daylight, apart from sunlight, is also known to be bactericidal, but daylight diffusing through ordinary glass has usually been regarded as inert because of the removal of the ultra-violet rays. Some of the ultra-violet light does in fact penetrate ordinary glass, and American work has shown that this diffused daylight is bactericidal. Ultra-violet light, though powerfully bactericidal against moist bacteria, is much less active against dried bacteria, and is largely inactivated by the presence of gross particles of dust. In spite of this Garrod has found that the dust in first-floor wards which were receiving a fair amount of daylight yielded a much lower proportion of streptococcus-positive samples than the dust of ground-floor wards whose windows were bricked up. Similarly, 42 samples of dust on black-out screens adjacent to the windows failed to yield any haemolytic streptococci, whereas 56% of the floor-dust samples were positive. This is only circumstantial evidence of the bactericidal activity of daylight through glass, and no doubt other factors were operative—for example, ventilation and variations in the source, composition, and degree of pollution of the dust. More direct proof of the bactericidal activity of daylight was afforded when films of naturally dried streptococcal pus placed in glass-covered Petri dishes and exposed to daylight through glass were sterilized in 6 to 19 days, a south light being rather more active than a north light. Control films in a dark cupboard yielded viable streptococci up to 110 days.

These tests and experiments give some support to a widespread belief that black-out and ward-protective restrictions in hospitals have a deleterious effect on patients and contribute to the risks of cross-infection. Besides the beneficial effect of daylight, proper ventilation is a great enemy of respiratory cross-infection, and both of these are too often sadly lacking in hospital wards at the present time. Cross-infection ceases to be a bogey in the summer months, and it has usually been assumed that better ventilation is responsible; but the part which daylight itself may play needs to be further assessed. Even if the bactericidal rays are not particularly active against dried bacteria they may, by attacking sprayed droplets in their still moist form, help considerably in preventing the accumulation of grossly infected dust. Daylight in the country and small towns is likely to be more bactericidal than that in our large cities, where most of the ultra-violet light is filtered off: this may be another argument for the transfer of hospitals into the country. The note by Shooter and Wentworth, printed at page 247 this week, on the fly as a carrier of haemolytic streptococci suggests yet another vehicle for the spread of this ubiquitous organism. Their finding may have special significance for surgical units with warmer weather and the "second front" ahead. It also emphasizes the lack of fly-proof screening in most of our hospitals.

## MONTE CASSINO—CRADLE OF WESTERN MEDICINE

Salerno is one of the very few places in the Roman Empire where lingered traces of the arts and sciences of antiquity. We commemorated it as the seat of the first medical school in our issue of Sept. 25 last, when it was occupied by the Allies. They have now reached Cassino, seventy miles from Salerno as the crow flies. The vast monastery on the mountain that overlooks the town has been a centre of learning from its very foundation. In the history of medicine it has a special place, for here the medical Dark Ages showed a spark of the new spirit. If Salerno connects the Dark Ages with the remote classical past, Monte Cassino represents the dawn of modern times.

The monastery is a huge mass of buildings which occupy the top of a conical hill. It contains a large cathedral church and a series of beautiful cloistered courts of various dates. The whole complex of buildings is connected to the little town of Cassino by a funicular railway crossing a gorge which takes the whole of a tiring day to traverse on foot. Of old it must have taken the best part of a week to reach the monastery from Salerno. The monastery was founded in 529 by St. Benedict of Nursia, who died there about 544. The monks still show his tomb and that of his sister St. Scolastica, together with an ancient wall and tower of comparable antiquity. Monte Cassino has had a varied and stormy history. In 580 it was sacked by the Lombards and was rebuilt in 720. It was nearly destroyed again by the Saracens in 884, and was again rebuilt about 950. It reached the height of its influence under its great abbot Desiderius, who became Pope Victor III in 1087. We need not pursue further the distinguished and eventful history of the great foundation. It is convenient, however, to recall that the Norman Conquest of South Italy and Sicily, which deeply affected Monte Cassino, was almost exactly contemporary with the Norman Conquest of England and took place during the abbottship of Desiderius. Monte Cassino is the acknowledged first centre

Western monasticism. The Benedictine Order has always been associated with the promotion of learning. In no part of its history did the reputation of the great house stand higher than at the time that we are considering.

In the eleventh century, the greatest period of Monte Cassino, the relations between the civilizations of East and West were the very reverse of those we now know. In our time we have seen Orientals accord to our civilization the sincerest form of flattery. Things were very different then. The West knew well that not only military might but also science and learning lay with Islam. Oriental efficiency in arms, in administration, in commerce, as well as in the sciences and arts, had been more than sufficiently proved. The impression that they made on their Western contemporaries is still enshrined in our language in such Semitic words as arsenal, admiral, tariff, algebra, almanac, theodolite, damask, and a hundred others. Not a few of these Semitic terms are medical. Among them, despite their Greek appearance, the medical reader may be sur-

prised to learn, are a number of anatomical terms such as the names of the basilic, cephalic, and saphenous veins, and, of course, the names of many drugs. The first to convey to the West the substance of knowledge on which Arabic influence was based was one Constantine. He was born about 1020, perhaps of Jewish parents. According to the common legend, he first saw the light at Carthage, but it is more probable that he was a native of Sicily. He acquired his medical knowledge in Jewish circles at Kairouan in Tunisia. This town, one of the last in Africa to be taken by the Allies, is one of the least modernized of Oriental cities. Constantine returned about 1072 to Sicily, then passing into Norman possession. There he came in contact with Robert Guiscard. In 1076 Salerno fell to the Normans and became the capital of a Norman principality under Robert. Constantine seems to have arrived at Salerno in his suite and to have acted as his secretary for Oriental languages. Having become a Christian, he retired about 1080 as a monk to Monte Cassino. There he spent his last years, translating Arabic medical works into Latin. He died in 1087. In the eleventh century the works of the ancient Greek physicians had long been lost in the West. Arabic translations of these existed, as did many works in Arabic based primarily upon them. The knowledge of these was, however, confined to those who could read that language; in other words, so far as the West was concerned, exclusively to Jews. The Arabic superstructure on Greek medicine had profoundly affected the whole outlook of the world of Islam. The advent of Latin translations of these Arabic works caused a similar stirring of the spirit in the West. Thus the writings of Constantine, being the very first of their kind, are of peculiar interest. They consist entirely of translations of Arabic-speaking physicians. Among them were several works of the centenarian, Isaac the Jew (855-955), the great physician of Kairouan. They include his work on fevers, the best of its kind for many centuries, another on diet, and a third on urines, as well as certain of his philosophical writings. There were also works of Isaac's pupil, another Jew of Kairouan, ibn al-Djezzar (924-1004), including his *Viaticum peregrinantis*, a very popular guide to travellers on the care of health. Very important was a version of an extensive work by the Persian Magian, Ali ibn Abbas (died 994), which, oddly enough, was also circulated in the name of Isaac. These works and others of the like kind provided a vocabulary of technical terms, the remains of which can still be traced in our medical nomenclature.

Despite the vicissitudes of the great monastery where Constantine rendered this first service to medicine there still remain in the library some fourteen hundred manuscripts of great antiquity. A considerable number of these are medical and of the time of Constantine himself. Some are of yet earlier centuries. There is also evidence, into which we cannot now enter, that some of Anglo-Saxon medical texts that are of the time of the Norman Conquest were prepared at Monte Cassino. On this account, as well as for their value as monuments of civilization, we rejoice to learn that these most precious documents were long ago removed to a place of safety.

## OESTROGENS AND THE OVARY

Fundamental discoveries in endocrinology were made at a time—about fifty years ago—when only crude glandular extracts were available for endocrine research. But many conclusions were reached on the basis of what seemed fitting rather than on actual observations. Such were Brown-Séquard's claims for the rejuvenating action of testicular extracts, and under the same heading must be placed scattered references to a stimulating action of ovarian extracts on the ovaries. With the discovery of the chemical nature of the ovarian hormones and the isolation of pure chemical products these claims were not substantiated. Recent evidence, however, suggests that oestrogens do in fact stimulate the ovary. An interesting series of papers on this question was published in 1942 by Bullough, who belongs to the school which believes that oogenesis proceeds in the ovary throughout life. Whether this is true or not does not detract from the value of his observations. Bullough first studied<sup>1</sup> the number and position of the mitoses in the germinal epithelium of the mouse ovary at the different stages of the oestrous cycle, using the colchicine technique to ensure that enough mitoses were available for comparative counts to be made. Colchicine causes the arrest of all mitotic divisions in the metaphase, which is easily seen microscopically. Thus in an animal killed 9 hours after an injection of colchicine all the mitoses that have occurred in this period will be incomplete and all may be counted. The average total number of mitoses in the germinal epithelium of each ovary he found to be 20 to 31 during the three days of dioestrus, rising to 81 during pro-oestrus, followed by an enormous increase during oestrus, a total of 1,210 mitoses being recorded as a post-ovulation peak, with a rapid fall to 100 mitoses during metoestrus. He then studied the distribution of the mitoses, and though there was some variation in their number in all positions the greater part of the increase found during post-ovulation oestrus was in those areas of the germinal epithelium adjacent to the developing corpora lutea (actually 997 of the total 1,210 were situated there). Bullough suggests that the increase in the number of the mitoses in this place is due to its being bathed in the oestrogen-rich follicular fluid extruded in ovulation. In support of this view was the fact that mice with fewer follicles than normal, or in which a smaller number of follicles ovulated, had fewer mitoses. Bullough then proceeded<sup>2</sup> to see whether this idea of the action of oestrogen on the mitoses of the ovarian cells could be supported elsewhere. To do this he divided the membrana granulosa and theca of the developing follicles into zones and counted the number of mitoses in each after an injection of colchicine. He found that the number of mitoses is greatest in those follicle cells nearest the oocyte and the antrum, and diminishes progressively towards the periphery of the follicle. In the developing corpus luteum mitoses are at first most frequent in the old granulosa cells nearest the extruded follicular fluid, but later they become common in the cells adjacent to the newly formed reservoir of tertiary follicular fluid. Lastly, he proved<sup>3</sup> that the effects attributed to the follicular fluid are due to the oestrogen it contains. Large doses of oestrone (25 µg. at twelve-hourly intervals in 1 to 5 injections) were injected intraperitoneally into dioestrous mice as near to the ovaries as possible. The mice were killed 12 hours after the last injection and 9 hours after an injection of colchicine. In all cases there was a stimulation of the mitoses in the germinal epithelium, a total of 1,818 being

counted in one ovary after 5 injections. The injections also reduced the normal rapid growth of the follicles, particularly of the larger ones.

Bullough concludes that oestrogen directly stimulates the ovarian cells. Theoretically the objection may be raised that since the mice had intact hypophyses a possible action on gonadotrophin secretion cannot be ruled out, though this does not seem likely in view of the time relations involved. Bullough himself regards the fact that the injections have to be given in the neighbourhood of the ovary as strong evidence of direct action, though many substances are absorbed more rapidly from intraperitoneal injections than from subcutaneous ones. However, these arguments are not really essential, since it has been shown by Williams<sup>4</sup> and by Pencharz<sup>5</sup> that the atrophy of the ovary which normally follows hypophysectomy can be prevented by the implantation of stilboestrol tablets, clearly showing that oestrogens can influence the ovary in the absence of the pituitary gland. The dose necessary to produce these effects is large, though Bullough's observations during the normal oestrous cycle suggest that the action is physiological. The full theoretical implications of the findings and their possible clinical applications remain to be studied.

## "BRITISH MEDICAL BULLETIN"

The first number of the second volume of this bulletin—on penicillin—starts the second year of its most successful career. The *B.M.B.* is published by the British Council and forms an important part of the activities of the Council's Medical Department, under the direction of Dr. N. Howard Jones, who is now a whole-time officer of the Council employed on this important task of informing medical men in other countries of the work that is being done by British doctors.

The *B.M.A.*, and more especially the *Journal*, has an interest in this undertaking and can take some pride in the successful way it has been carried out, for it was in 1940 that informal conversations were held between the Medical Research Council, the Ministry of Information, and the Editorial Department about supplying trustworthy information to foreign and friendly countries in order to create a basis of fact against which the foreign reader could judge misrepresentations made by the enemy. It was finally agreed that the war was proving a stimulus to a course of action that should have been entered into long before, and it was soon decided that the diffusion of medical knowledge from this country should be embarked upon as a long-term policy, and not as a short-term attempt to counter the absurd propaganda put out by the Germans. Dr. Howard Jones was appointed in August, 1940, to carry out this work in the Editorial Department of the *Journal* under the Editor's direction, and a scheme was prepared for sending to different parts of the world abstracts of important articles in current British medical journals, translated when possible into the language of the recipient country. Original articles by leading medical men on work in which British scientists had played a large part were also written, translated, and submitted for publication to foreign medical journals. Although some of the abstracts found their way to the bottom of the ocean, many were eventually printed in the foreign medical press, and medical editors and individual medical men abroad expressed their appreciation of the fact that at last this country was doing something to keep others informed of what was happening here in medical science. At the end of a year the basis of the British Medical Information

<sup>1</sup> *J. Endocrinol.*, 1942, 3, 141.

<sup>2</sup> *Ibid.*, p. 150.

<sup>3</sup> *Ibid.*, p. 235.

<sup>4</sup> *Nature*, 1940, 145, 388.

<sup>5</sup> *Science*, 1940, 91, 554.

Service, as it was then called, was firmly established, and at this point the British Council, which had been supporting the work from its beginning, suggested that they should now take it over completely as a permanent part of their activities, and in October, 1941, Dr. Howard Jones and his small staff left B.M.A. House for Hanover Street. The Council has recently begun to produce medical films, one of which, "Surgery in Chest Disease," is now familiar to many.

The *British Medical Bulletin*, the latest issue of which has suggested to us that we should put on permanent record the short history of the British Medical Information Service, developed out of the abstracting service and is fast becoming a real contribution to medical literature. It is published in English, Turkish, Portuguese, and Spanish. Recently the tendency has been to make each number a symposium, and the present one on penicillin provides a document which is almost indispensable to anyone who is working on this subject and who really wants to know the literature on it up to date. The symposium begins with six articles on various aspects of penicillin by Prof. L. P. Garrod, Prof. A. Fleming, Dr. E. Chain, Prof. H. W. Florey, and Dr. M. E. Florey. Then comes a review of selected papers in order of publication, beginning with 1929 and ending with 1943. A short appendix follows. The care and thoroughness with which this excellent symposium has been put together are a great credit to the compiler.

#### EUGENIC AND GENETIC ASPECTS OF THE Rh FACTOR

Many recent papers have added to our knowledge of the Rh factor and its responsibility for the great majority of cases of erythroblastosis foetalis. Haldane<sup>1</sup> has made an interesting contribution to this discussion, for he shows that important questions arise in the field of population genetics and of practical eugenics. Nine out of ten cases of erythroblastosis foetalis are due to the development in the blood of an Rh-negative mother carrying an Rh-positive foetus of immune bodies capable of agglutinating Rh-positive red cells. About 10% of all pregnancies among white American or British mothers are of this type, so at an additional factor, probably placental permeability, must also be involved. Haldane adopts the conservative estimate of a death rate from the condition of 1 in 200 conceptions, so that the abnormal permeability occurs in about 5% of cases. Using the above figures, he shows that the existing 14% or so of Rh-negative persons would be reduced to 1% in little more than 600 generations, or 15,000 years. This is a short time in the history of the human species, so that the existing population must be in a state of highly unstable equilibrium. Haldane discusses three hypotheses which could account for this strange state of affairs. The first is that recent environmental changes have led to a sharp increase in placental permeability: all the available evidence is against this possibility. The second is that the heterozygous state—that is, the possession of one Rh-positive gene and one Rh-negative gene—confers some counterbalancing advantage. This hypothesis is equally unlikely, for it would demand a favourable effect many times greater than the highest possible limit for the ordinary blood-group genes. The third hypothesis remains—that the present unstable proportions are due to recent racial mixture. Any human community would, left to itself, fairly rapidly become almost uniformly Rh-positive or, alternatively, Rh-negative, save for rare exceptions due to mutation. It is possible, therefore, that the European races have arisen in the not very distant past from the crossing of Rh-positive and Rh-negative races, and

are now undergoing a process of swift change. The study of Rh frequencies in different populations is thus likely to prove of high interest anthropologically. Haldane notes that it has already been discovered that only one out of a series of 120 North American Indians was Rh-negative. He points out more generally that variation in placental permeability and intense selection against heterozygotes may have been one of the mechanisms by which mammalian species have become distinct.

Haldane suggests that erythroblastosis foetalis provides a concrete test case for the advocate of negative eugenics—a case, moreover, which cannot be ignored, for this disease is certainly responsible for more deaths than are due to any other inherited condition. It is obviously futile to suggest that the 14% of Rh-negative women should not marry Rh-positive men—that is, that 86% of the male population should be barred to them. Nor could it be seriously suggested that the Rh-negative character ought to be eliminated by sterilization. If it should be found, however, that the abnormal placental permeability also depended upon a gene, he considers that there would be a strong case for dissuading women with the doubly unfavourable constitution (less than 1% of all women) from marrying Rh-positive men, and an arguable case for compulsion. But if the eugenic problem cannot be ignored it can, as Haldane goes on to show, be evaded. He suggests that the testing of pregnant women for the Rh factor, and if found negative, then further testing for the anti-Rh agglutinin, would give timely warning of the risk of erythroblastosis foetalis and facilitate prompt treatment by transfusion with appropriate blood. Actually this is no longer speculative. Since his paper was written Gimson<sup>2</sup> has described in this *Journal* a highly successful series of cases, and is able to conclude that, if an infant suffering from the condition lives long enough to reach hospital, there is a good chance of survival. In fact, up to now this is the finest example of an application of genetic research leading to the chance of timely recognition of a great danger and thus to prompt and successful treatment.

#### STANDARDIZATION OF NON-IONIZING RADIATIONS

The Medical Research Council has appointed the following as a committee to advise and assist it in promoting the quantitative study of the non-ionizing radiations, particularly in relation to their medical applications: Prof. H. Hartridge, M.D., F.R.S. (chairman); F. Bauwens, M.R.C.S.; R. B. Bourdillon, D.M.; E. Rock Carling, F.R.C.S.; Prof. J. A. Carroll, Ph.D.; J. Guild, F.Inst.P. (nominated by the Department of Scientific and Industrial Research); Prof. F. L. Hopwood, D.Sc.; and Prof. W. V. Mayneord, D.Sc. (secretary). In 1928 and 1937 satisfactory units for the measurement of ionizing radiations were agreed internationally, and there is urgent need of a corresponding standardization for the non-ionizing radiations. Under this heading will be included infra-red, visible, and short-wave wireless radiations, but it may be found advisable to deal also with ultra-violet and ultrasonic radiations, since none of these was covered by the earlier recommendations.

We regret to announce the death of Mrs. Frances Ivens-Knowles, M.S., F.R.C.O.G., late clinical lecturer in midwifery and gynaecology in the University of Liverpool, and during the last war surgeon-in-charge of the Scottish Women's Hospitals at Royaumont and Villers Cotterets.

# DILAUDID

Trade Mark

dihydromorphinone

Brand

## Improved Morphine Preparation

Whilst the analgesic power of "Dilaudid" is five times as great as morphine its hypnotic effect is considerably weaker. In the derivative, the euphoric element is largely subdued and the risk of addiction correspondingly lowered. Tolerance is greatly improved, an increase of dosage rarely necessary. The effect on peristalsis is only slight and much less persistent than in the case of morphine.

# DICODID

Trade Mark

dihydrocodeinone

Brand

## Powerful Antitussive

Occupying a place midway between morphine and codeine, "Dicodid" exerts a specific and selective action on the cough centre. The absence of any notable constipating effect is responsible for the use of "Dicodid" as a post-operative analgesic. Better tolerated than morphine, "Dicodid" also interferes very much less with expectoration.

Available in the form of oral tablets, ampoules, hypodermic tablets, and suppositories.

# In Childhood... and Adolescence

In childhood and adolescence, the total haemoglobin increases with growth, and the store of iron in the body must be maintained proportionately. It is acknowledged that this added need for iron may be difficult to obtain from the food and, consequently, must be supplied as medication. Excellent results are offered by the use of specially prepared iron (easily assimilated ferrous sulphate) incorporated in 'Plastules.'

Formula: Exciticated Ferrous Sulphate B.P. 5 grains, Dried Yeast 1 grain, Excipient sufficient quantity

## Sterilised SULPHANILAMIDE

'Wellcome' brand Sterilised Sulphanilamide has been introduced for implantation into closed cavities or application to surface lesions. This is in addition to 'Wellcome' brand Sulphanilamide Compound (containing 5 per cent of Zinc Oxide), an exceptionally free-flowing powder for use on surface lesions and open wounds. Both preparations are packed in the new 5 gm. double envelopes, specially designed for speedy application with complete asepsis, as well as in 15 gm. sealed bottles.

## Nova et Vetera

## Correspondence

## FIRST AID 140 YEARS AGO

Though the term "first aid" was not invented in his time, yet Dr. William Buchan's *Domestic Medicine, A Dispensatory for the Use of Private Practitioners*, published in 1804, was really an early attempt to give the general public some systematized advice on how to deal with accidents and illnesses before the arrival of the doctor, though in some respects the book goes far beyond this. For his "private practitioner" was the layman pure and simple. It may be of interest to see what the person whom we should now call the first-aid-er was expected by our author to do.

## Some Drastic Measures

For one thing, he was expected to apply some heroic measures which will make the hair of the modern reader stand on end. An instance of this is the method recommended for the reduction of what Dr. Buchan calls "Dislocation of the Neck." He advises that the "unhappy person" should be laid on his back while the good Samaritan takes hold of his head with both hands, braces his knees against the patient's shoulders, and pulls the head "with considerable force" while "gently twisting it at the same time," if the face be turned to one side, until he perceives the joint to be replaced, which the operator will know "by the noise the bones make when going in." After this, the patient is to be bled and suffered to rest. We shall probably agree that the phrase "unhappy person" is not a whit too strong. On dislocation of the jaw he is sounder, giving a method very similar to our own. But he also mentions a drastic method used by the "peasants" which, he tells us, he has often known to succeed, though he does say the plan is "dangerous." It is. For the "peasant" puts a handkerchief under the patient's chin then turns his back on the dislocatee and pulls him up by the chin so as to suspend him from the ground.

Much of his advice on how to deal with "Substances stop'd between the Mouth and Stomach" is quite common sense, though we can hardly approve of his plan, "if fingers and nippers fail," of "bending a piece of pretty strong iron wire at one end," introducing it on the flat below the obstruction, and pulling it up. He advises, cautious man, that a piece of string be attached to this instrument in case of "ill accidents" such as slipping from the operator's hand. His method of artificial respiration, however, is quite passable if we remember that he wrote before the advent of Silvester, Schafer, and Eve. Dr. Eve, indeed, would quite approve of his insistence upon the necessity for restoring "the natural warmth" as a "principal intention." He himself favours immersion in a warm bath after or during the application of mechanical measures such as blowing by a "strong person" into the patient's mouth with the nostrils stopped, and pressing the "breast and belly" so assist expiration. But other measures he mentions to restore the natural warmth are somewhat drastic. One he quotes with approval is to lay the body on hot ashes, cover with ashes equally hot, put a bonnet on the head, and wrap a stocking filled with hot ashes round the neck. He does not altogether disapprove even of the method which, he says, is used in some parts of the countryside—viz., to make use of the warmth of a dunghill.

## Immediate Treatment of Wounds

Dr. Buchan's general directions for the immediate treatment of wounds are very sensible considering that he wrote before asepsis and antiseptics had been thought of. He ridicules the implicit faith placed in "certain herbs, ointments, and plasters as possessed of wonderful healing powers," insists that Nature does the cure, and explains that external applications assist only by keeping the parts "clean, soft, and defending them from the external air." For this purpose he recommends clean, dry lint as a first dressing. He is not so sound, however, in resorting at once to the tourniquet when there is haemorrhage, nor does he give proper warning as to the dangers incurred by improper use. He, of course, knows nothing of "pressure points"; indeed, he does not even so much as mention any form of digital pressure.

His advice on the treatment of fractures is more applicable to the professed surgeon of his day than to the "private practitioner." He does, however, give a much-needed caution as to the danger of tight bandages. On the general application of bandages to various parts of the body, however, he gives no directions, being of the opinion that any person of good parts will be able by native genius to apply them correctly!

Space has only allowed me to pick out some of the high spots in this curious treatise. In justice to the author, it must be owned that he is, on the whole, not unsound according to his lights. It is therefore all the more surprising when we come upon passages like some cited above and like the one in which he gives his sanction to the employment of fresh cow-dung poultices in the immediate treatment of bruises.

E. W. A.

## Publication of Anaesthetic Misadventures

SIR.—May I seek the courtesy of your columns to make an urgent request to all anaesthetists to publish a record of deaths and untoward incidents occurring under any form of anaesthesia and analgesia. Two deaths under local analgesia have been briefly recorded during the last five weeks in the *Evening Standard*, and it is a matter for regret that these deaths were not fully reported in the medical journals, as local analgesia has been generally regarded as very safe.

Anaesthetic mortality and morbidity in this country is far too high, and it does not at present seem that a noticeable drift away from inhalation anaesthesia and the adoption of other methods are leading to improved results; rather the reverse. Newly qualified practitioners often appear to have a very imperfect understanding of the relative safety of various anaesthetic techniques, and this unhappy ignorance may be the cause of avoidable deaths.

Under an entirely erroneous impression that ether leads to chest complications some anaesthetists are adopting the use of new and somewhat dangerous drugs, the physiology of which is as yet imperfectly understood. A false sense of security will arise and "modern anaesthesia" will become (if it has not already done so) far more dangerous than chloroform anaesthesia at its worst, unless practitioners are prepared to publish the complete records of all misadventures experienced during the experimental stage. Let it be remembered that many modern anaesthetic methods have not yet passed the experimental stage and we need much more information. The Association of Anaesthetists could materially assist by organizing a large-scale investigation as to the relative danger or safety of all anaesthetic drugs and the manner of using them.

There is at present a strong tendency to gamble safety for comfort, and this tendency is strengthened by ignorance caused by a very natural reluctance to publish our misadventures and a readiness to publish records of a series of our cases successfully anaesthetized by some new technique; thus a too optimistic picture of the real position is given. The investigation into analgesia in labour published by the Royal College of Obstetricians and Gynaecologists in 1936 showed how misleading individual experiences can be, and that a series of two or three thousand cases really shows us very little. Flagg, too, in his *Art of Anaesthesia*, stresses how inadequate is the experience of any one individual, however great that may be, to form a basis for a true statistical estimate for the guidance of others. We must take a wide view, and we can only come to a right judgment by co-operation and complete frankness. The American journals set us a very good example in this respect. Nothing can be gained by silence, and the general public, too, might then begin to understand their foolishness in not paying more attention to the importance of the art and science of anaesthesia. It is utterly lamentable that a surgeon should tell us in 1944 that in a county hospital "the anaesthetics are given by house-surgeons, many of whom have no previous experience" (O'Connor, *British Medical Journal*, Feb. 5, p. 199).

—I am, etc.

JOHN ELAM.

New Barnet.

## Chloroform Anaesthesia

SIR.—Recent letters in the *Journal* on the teaching of anaesthetics have drawn attention to the need for some improvement. I should like to see a crusade against the use of chloroform. Most authorities concede that the use of chloroform might possibly be justified in certain circumstances in the hands of an expert. Instead of this we find that the expert has abandoned chloroform altogether, and the only people using it, or mixtures containing it, are the inexpert, such as the resident, giving anaesthetics in the absence of the resident anaesthetist, or the overworked G.P. If there were better teaching of anaesthetics these people would understand the risks they run in using such a dangerous and toxic drug.

Almost at once after the induction of chloroform anaesthesia there is a fall in blood pressure. This fall is caused by heart failure

alone, and the heart may even fail before respiration. (This never happens with any other anaesthetic agent.) Levi was one of the first men to draw attention to the dangers of ventricular fibrillation under *light* chloroform anaesthesia, and to point out that the *deeper* the degree of anaesthesia the greater the chances of recovery. Blalock in 1928 recorded that the cardiac output in a series of eight dogs under ether increased an average of 20%, whereas with chloroform the cardiac output was decreased an average of 30%. Two hours of chloroform anaesthesia have been proved to be followed by liver changes which take 6 weeks to return to normal. Those who ridicule the dangers of chloroform do so chiefly from ignorance of these proved physiological facts.

Chloroform certainly has no place in the hospital; it may possibly be of use where no other anaesthetic is available—for example, in a ship at sea. Boyle's apparatus with chloroform and ether in series is potentially a danger. The chloroform bottle might now be discarded, and even were it needed, why is it not placed after the ether instead of before it? Were this so, at least we should only get chloroform polluted by ether, and not be found giving fifty-fifty chloroform-ether with only the ether tap turned on. Where there is risk of explosion there are now many agents we may use without having to resort to chloroform, such as intravenous pentothal or evipan, perhaps supported with gas-and-oxygen; gas-and-oxygen alone or supported by trileuc; in thoracic surgery, unilateral spinal; and for, say, exploratory laparotomy light percaïne spinal.

It will probably be a considerable time before all anaesthetics are administered by experts, but at least we should demand that all who are called upon to give them should have a reasonable knowledge of their dangers.—I am, etc.,

H. PARRY PRICE.

### Blood-pressure Readings in General Surgery

SIR,—May I reply to those who commented on the article on this subject (Dec. 25, p. 811).

To Mr. J. Hosford (Jan. 8, p. 59) I would say that blood-pressure readings can be done in all hospitals and should be taken in teaching hospitals where student help is available. Surgeons who have enjoyed the assistance and the instruction that these regular pressure records give must articulate their value so clearly and convincingly that they ultimately become as routine at operations as counting swabs.

With regard to deaths on the table, may I repeat that when blood pressures are taken during operation patients never reach the stage of death, actual or impending, without the entire surgical team being warned for some time previous, and their united efforts are directed to resuscitation. When such a crisis occurs, the instruction of the readings assists in the selection of the remedy and its correct dosage, for too little or too much may be given. Our pressure observations enable us to say that certain drugs given in a certain way will in a certain time act in a certain amount for a certain period; these include ephedrine, pholedrine, methedrine, cardiazol, coramine, and paradrine among others. So valuable are blood-pressure readings that a recorder of them at major operations is arranged for in the same way as the anaesthetist.

I assure Drs. Fearnley, Langton Hewer, and Morgan Jones (Jan. 15) that besides the blood pressure the other factors they mention are considered, but the short article omitted to state this; it attempted to evaluate the blood pressure for surgeons.

I am aware of the danger of a failing left heart; for instance, I find it difficult to diagnose clinically between it and an early carcinoma of the stomach. Likewise I have seen a patient recovering from a coronary infarct with a blood pressure of 130/90 superficially by the cardiac index alone a good surgical risk, yet the output of that heart was irregularly irregular (negating operation) and the history told of a prethrombotic pressure of 220.

The variation in blood pressure from observer to observer and from time to time was noted in the article, but the cardiac index as a rule is approximately constant, and the improvement from rest in bed and other remedies, estimated by my house-surgeons, blood-pressure reader, and myself, has been confirmed. The stimulants are given by the mouth—usually coramine, cardiazol, or strychnine (a general rather than a cardiac tonic)—and for the irregularly irregular rhythms digitalis, although auricular fibrillation is comparatively rare in surgical practice.

Patients needing operation are not denied them because of the cardiac index, but they may be prepared for several weeks

until they are deemed fit enough, and salutary experience confirms its necessity. Catastrophes in the cardiovascular system occur often enough to require its critical evaluation, and I repeat that the blood pressure intelligently taken will reveal significant information and with the cardiac index will be found a guide in the general run of operation patients.

With regard to the high pre-operative intake of fluid, experience shows that patients need it before a major operation. I know that in the treatment of heart disease fluids are limited deliberately, but when the cardiac lesion is as gross as this, preparation for operation is the physician's responsibility, and operation at this time is usually out of the question.

I like Dr. Langton Hewer's expression of the anaesthetist's problem, "not 'Can this patient survive my anaesthetic?' but 'Can I improve his general condition sufficiently to enable him to withstand the surgical trauma, and to live long enough to benefit by the effects of the operation?'" It is a charter for the physician-anaesthetist and the surgeon too!—I am, etc.,

London, W.1.

HAROLD DODD.

### Obstetric "Shock"

SIR.—The condition of obstetric shock requires the clearest definition, and I should like to elaborate Dr. Alders's admirable letter (Feb. 5, p. 197). The shock following obstetric mishandling is clearly surgical shock and has no place in this discussion. Its incidence should diminish when the three great causes of obstetric intervention—expediency, fear, and clamorous relatives—are given their correct place in our judgment.

The second, more nearly related, shock is that caused by pituitrin. The incidence of this too will, I hope, decrease when pituitrin is no longer given as a routine, a procedure which can be justified neither by reason nor by necessity. The shock it produces is sometimes thought to be a protein reaction, but I believe the mechanism to be the same as that causing true obstetric shock—the sudden release of a shock-producing substance (histamine, if you will) from the damaged muscle fibres in the uterus. These fibres have already shortened to the minimum physiological length, a process unique in duration and degree. Moreover, they are required to "hold" this shortening. The resulting relative anaemia does not allow the waste products of this immense effort to escape; the subsequent relaxation of the uterus is, I believe, concerned solely to allow these products free exit. It is therefore the worst possible obstetric practice to over-exert these gasping fibres with pituitrin, or to damage them with the manual *csuminess* of Credé's expression, a procedure again too often dictated by expediency or fear. Although true obstetric shock is so seldom seen, the tolerance of the uterus is no excuse for insulting it.

Blood transfusion, though empiric in reason, is admirable in treatment. When, however, we replace in our minds the fear of the third stage of labour, from which all of us have suffered or do suffer, with the quietness and confidence of uterine understanding, the necessity for such treatment will be minimized.—I am, etc.,

London, W.1.

MORTIMER REDDINGTON.

### Rehabilitation: A Warning

SIR.—This letter is not designed to be destructive. For three years now I have had the opportunity of following up, in most cases by weekly interview, those injured at the factories of a group of 8,000 workers. In many of these cases I have seen the place at which the injury occurred and know how the accident happened. In some cases I know, or at any rate try to find out, why it happened. In all cases I have tried to get some idea of the make-up of the injured workman and how he lives.

It is clearly right on moral grounds that every injured workman should receive the most skilful treatment and be returned to work with as little disability as possible. To this end it is clear that the support of industry and companies carrying the risks of workmen's compensation should be given to hospitals which aim at providing the highest standard of surgical care. From observations made on 1,000 workers admitted to compensation I would plead that it is necessary to move slowly in estimating the value of rehabilitation. Is not the word becoming almost mystical? One cannot but be amazed

the initiative of many injured in overcoming any disability, even when the architecture of first treatment has been faulty, is the surgeon made sufficient study of those who have apted themselves to their disabilities? It is doubtful. The first essential is first-class first treatment. The number of those who will benefit by an elaborate machinery of habilitation is not as large as some think. True, for patients with major injuries and those with a necessarily long absence from work rehabilitation is absolutely essential. It is the care of this type of case which has attracted public attention, and rightly so. Rehabilitation without the insurance of a planned turn to work is a mockery and can do grievous psychological damage. But among patients suffering from less major injuries believe there are a number who will show through rehabilitation an unnecessary delay in returning to work. They are those who, with the utmost care of the staff of the rehabilitation centre, will surely become over-interested in themselves and tend to fix their minds on the injured part. Many patients are harmed by the unguarded advice of those who treat them, alighting in the series of cases I have seen is almost consistent. If, as I contend, there is a delay through rehabilitation the return to work of those with less major injuries, then is a serious matter. Full function must be our aim whatever the cost, but the cost must be reasonable. A man's own initiative is still the best second to first-class surgical care. The extra weeks on all these non-major injuries would mount a cost beyond a reasonable figure, and if the State takes over the workmen's accident insurance it must operate without extravagance.

This letter is but a warning that rehabilitation may so easily be overdone, and such a useful advance lead to some abuse cannot much rehabilitation be done in the factory, much of it on the workers' original work?—I am, etc.,

W. JEATFRESON LLOYD

Works Medical Officer

Guest, Keen and Nettlefolds Ltd.,  
Birmingham

### Doctor and Patient

SIR,—I am astounded that in your annotation on doctor and patient (Feb. 5, p. 189) you should see fit to state: "It is very wrong, therefore, for a private practitioner to attribute banal symptoms to industrial processes of which he knows nothing, to give long holidays for trivial maladies, or to declare a worker unfit for a particular job on eleemosynary rather than scientific grounds." These are so obviously the words of a writer who is quite ignorant of the medical situation in an industrial area that they call for correction. Quite apart from the specific lesion—such as industrial dermatitis or silicosis—which is caused by industry, the whole industrial set-up imposes upon the individual a discipline and a compulsion which, in the case of the rebel and the emotionally unstable, often become unbearable. It is precisely when health is lowered that this strain is most acutely felt by the patient.

It is all very well to talk about science, but there is no science without public standards, and there are no public standards for this situation. Psychology is still looking for them. Eleemosynary is a word meaning charitable, commonly used by the uncharitable. The argument therefore is that the worker in the hour of his complaining requires science but not charity. Is this really editorial opinion? Surely what these patients need from their doctor is just plainly charity, and it is to the credit of general practitioners that they commonly get it.

If the industrial set-up did its job with more success, if it gave us a stable economy, if it contributed to the integrity and well-being of the family, if it made our cities beautiful and the insight of the common man more profound, then perhaps the doctor would be justified in inviting his patient's co-operation in these good and charitable works. But unhappily industry does none of these things, and its insight into the nature of human need is superficial in the extreme. Its development of human skill is subject to question. And the quality of the community life that goes on in the back streets of our industrial towns is something which I for one cannot contemplate with complacency.

The common working doctor does well if he stands by the common working man in good will and charity. Science cannot

yet provide him with infallible guidance in this territory. Every clinician recognizes that outside the realm of definite diagnostic labels there are many indefinite debilitated states that are little understood and subject to variegated labelling. The general practitioner knows perhaps better than the leader-writer the need for science. But his need is for a science which will give an account not only of the fragments of disease but also of the whole—of healthy persons in a healthy setting. Such a science will lay down the scientific as distinct from the moral standards of family and community life. To these it will be the duty of industry to conform. To invoke science as the only sanction for a label which will permit the worker to lay down for seven days the burden of his obligation to the Work State is by way of being rude to Science. It is to use a good thing ill.—I am, etc.,

Coventry.

K. E. BARLOW.

### Reform in Medical Education

SIR,—Dr. Walshe has framed a cogent indictment of the medical curriculum as it stands and of the proposals to amend it by additions. Many hearts must sink at the thought of the poor patient camel of a student kneeling to receive his eighty lectures of psychologists' psychology to top his present burden, and many must marvel at the naivety which can expect him to become thereby a more "insightful" and less materialistic practitioner.

But Dr. Walshe does not, as I think, carry his argument to its logical conclusion. He points out that the curriculum fails to teach clear and logical thinking and the right use of words; that it encourages credulity and breeds practitioners and even teachers who "fail to distinguish between thoughts, words, and things," and who are unable to speculate fruitfully on the theoretical basis of medicine; but he seems to imply that these qualities of mind could be cultivated within the framework of a curriculum, pruned and revised indeed, but still a technical medical course of teaching. Surely the really disastrous consequence of the curriculum's unwieldy bulk and weight is that it has sunk into and destroyed its own foundations. The place and time to learn the right use of words in thought, speech, and writing, to acquire the habit of speculation and the beginnings of wisdom and understanding of the human mind, is at school in the sixth form—or its equivalent—between the ages of 16 and 18.

These acquisitions are a natural and almost inevitable accompaniment and consequence of the intelligent study of a foreign language—ancient or modern—with its literature, of our own literature, or of history. They are not a natural or inevitable accompaniment of the study of elementary chemistry, physics, and biology. If we want to have in our profession clear-headed thoughtful doctors able to express themselves lucidly and concisely, with a flair for truth and a contempt for muddled thinking, we must at least allow the intending medical student, to become a scholar if he has it in him. If we wish the doctor to understand men's minds we must at least allow him to read the thoughts they have expressed and to learn of their behaviour as recorded by historians, dramatists, poets, and the greater novelists. If we wish the doctor to think we must encourage and even compel the student to arrange and express his thoughts. At present it becomes harder every year for a boy who, at 16, rashly declares his intention to become a doctor not to abandon all hope of becoming also a well-educated man.

Is it not abundantly clear that to attempt reform of the curriculum by additions, however desirable in themselves, is a disastrous policy if the end in view is to produce a generation of doctors worthy of medicine and of their country? Subtractions, even by themselves, would be better. But subtractions, of course, will not serve. The only way with the curriculum, if our intentions are serious, is to "shatter it to bits and then remould it nearer to our heart's desire," and the remoulding must begin with the examinations which govern it. When at least one question in every paper begins with the word "discuss" and means what it says, and when one paper in each examination is an essay paper, carries high marks, and is judged on form as well as content, we shall be getting on.—I am, etc.,

London, N.W.3.

LINDSEY W. BATTEN.

### Research in Ophthalmology

SIR.—The letter on research in ophthalmology from the president of the Association of British Ophthalmologists (Jan. 29, p. 158) is one which I hope will commend itself to most ophthalmologists. I have heard no contradiction of the view frequently expressed by me and by others that research in ophthalmology, with the closely allied activity of "prevention of blindness," while being of high quality, has not in the past been attacked with a vigour comparable with its great importance. The humanitarian and financial responsibilities resulting from blindness are of a considerable magnitude.

These basic considerations have been debated in the Prevention of Blindness Committee of the National Institute for the Blind for the past five years, and the committee reached a decision that the most effective way of reducing the incidence of blindness, now that surgical technique has attained such a high standard of efficiency, would be to institute independent but co-ordinated centres of research in certain universities and Royal Colleges. Two such centres have already been established—one in the University of Oxford and another jointly by the Royal College of Surgeons and the Royal Eye Hospital, London. Provision for further extensions of this important aspect of prevention of blindness is at present under consideration. As soon as this provision is authorized the junior members of hospital clinical staffs should be informed that for selected workers research in ophthalmology will offer a congenial career, comparable with other methods of the practice of their profession. Young clinical assistants with a flair for research will no longer feel that they are entering a backwater, and that their families will be financially penalized if they pursue research work for which they are specially suitable and for which they are willing to be trained.

I do not agree with Mr. Green, however, when he details as an alternative to this policy the creation of a Faculty or College of Ophthalmology. Such an advancement in ophthalmic organization is desirable and would be complementary and supplementary to the extension of facilities for research in teaching institutions, but it could never adequately replace such facilities. Successful research in ophthalmology implies the closest association with the basic sciences and with abundant clinical material.

I feel that no useful purpose can be served by attributing the neglect of research in ophthalmology in the past to any particular persons or group of persons. Rather should we recognize the great need for organized extension of facilities and concentrate on the best methods of making provision for such extensions. That certain universities and the Royal Colleges are suitably organized for carrying out such research under the most favourable conditions will, I hope, be agreed, and must be the method of choice in any comprehensive policy for the evolution of research in ophthalmology in the future.

Provision is also being made for the individual research worker, whose bona fides is established, through a minor research fund.—I am, etc.,

C. G. KAY SHARP.

Chairman, Prevention of Blindness Committee,  
National Institute for the Blind.

Leeds

### Actinomyces of Liver

SIR.—Mr. Hubert Chitty (Jan. 22, p. 115) reports the recovery of a case of actinomycosis of the liver. It would be interesting to know what treatment, if any, this patient received after his operation in Feb., 1929: whether the patient recovered as the result of the development of some immunity reaction or following the administration of iodine in some form or other.

There is an apparent contrariness in the results of treatment with iodine, whether given as iodide of potassium or tincture of iodine, some cases progressing to complete cure, others showing no improvement. This contrariness depends, so I believe, on whether there is or is not a secondary infection with pyogenic bacteria.

I have seen only five cases: the first, one of the lung with extensive cavitation and heavy secondary infection approaching the terminal stage. In the second, an abscess of the appendix with secondary abscesses, there was a secondary infection with *B. coli* not only in the primary but in all secondary abscesses,

which, when aspirated, gave a heavy growth of *B. coli* and showed typical actinomycosis granules; treatment with iodine was without effect; surgical treatment and packing with bipp resulted in death from nephritis due to bismuth poisoning. Nos. 3 and 4 were abdominal cases, operated upon, and reported by the pathologist as actinomycosis; there was no secondary infection, and both cases were cured by tinct. iodi (French Codex). No. 5 was an empyema. The surgeon remarked on the unusual hardness of the lung. Typical actinomycotic granules were present in the evacuated pus and in the sputum, but with no evidence of any secondary infection. Treatment with iodine in the form of tinct. iodi (French Codex) resulted in a cure, and the patient was still well and free from lung trouble 10 years later.

These cases seem to favour the theory that actinomycosis, like tuberculosis, is a much more serious affair when secondary infection has taken place. Recent reports on the cure of actinomycosis with sulphonamides suggest that it is in these cases where secondary infection has occurred that its chief advantage is likely to be reaped, especially if combined with iodine, and personally I like to give the iodine as tinct. iodi (French Codex), now known as the liquor iodi simplex.—I am, etc.,

West Malvern.

F. H. JACOB.

### Bone-marrow Transfusion

SIR.—Since the method is not yet in general use it seems worth while to second Mr. Hamilton Bailey's favourable testimony. By the intramedullary route I have given transfusions to forty infants under 1 year old, using the marrow of the tibia because the manubrium is not a good site in such small subjects. There was no difficulty at all, nor was any trace of sepsis encountered, though it was sedulously looked for in every case. The technique is utterly simple and the discomfort momentary. Any collapsed and dehydrated infant can have a transfusion under way within ten minutes of admission to the ward. Of course the clinical value of marrow transfusion is no greater than that of intravenous therapy by any other route: its virtue is purely technical. Still no one who has fumbled with a Bateman's cannula and a vein like a bit of chewed cotton, no one who has seen the last available venous channel firmly clotted up, no one hard pressed for time, once having tried this new method is likely to revert to the old. The only snag (barring over-enthusiasm engendered by facility) is the difficulty at the present time of getting needles sharpened.

One more point: some time ago in your "Any Questions?" column I saw mention of a serum needle for marrow transfusions. This is to be deprecated. Tocantins's needle, well and stoutly fashioned for its special purpose, is the weapon of choice.—I am, etc.,

The Grove Hospital, S.W.17.

J. B. ELLISON.

### Babies in a Glass Cage

SIR.—Some publicity recently has been given in a number of lay periodicals to the design and equipment of the new Children's Hospital, Birmingham. The public are told, journalistically, of our backwardness in baby welfare in this country, but that at least one step has been taken at Birmingham to put this right. Here "the idea behind is isolation." Ill babies are placed in glass cubicles isolated from friend and foe. They are suckled, if necessary, by a mother whose face has been obliterated by a mask and from a nipple whose attendant beloved breast is shrouded in a harsh, unlovely, but sterile gown. Bathing is conducted by a similar fantastic creature, but without even the beloved voice of mother to give a shred of comfort to the lost, ill, and hereft infant. After bathing (and feeding) the patient is placed in its cubicle of isolation behind whose refracting glass walls human figures appear and disappear with fantastic inconsequence, and through which the homely human sounds penetrate dully, a dim reminder as from a distance—a distance into which all the lovely, comforting, satisfying, and familiar things seem to have receded.

From this brave new world of deprivation, insecurity, soundlessness, and terrifying sights the infant victim is expected to draw fresh reserves with which to combat the invading micro-organism. How can it? Can the frustration of practically

very strong emotional need possibly cure an infant of anything? Do we, the medical profession, advocate a treatment which, I earnestly suggest, must be, for the patient, so much worse than the disease? Even if it is not, as it may be, ethal, what of the immediate misery and the ultimate consequences to mental health? Already we have with us the "evacuation problem," product of these same experiences of sudden deprivation, insecurity, and fear in older children. How much worse will be the effect on the still more sensitive 1-1-year-olds!

The general case for the control of sepsis in hospital practice—mainly surgical—is of course unanswerable, but that asepsis should be given an overwhelming emphasis in the treatment of infants is more than doubtful. With Bakwin's paper—reported in an annotation in the *Journal* of Sept. 19, 1942—offering unquestionable statistical evidence to the contrary, whatever case there was falls to the ground. Certainly submitting our frailest patients to such a fantastically severe regime should not be accepted without question as a self-evident triumph of science. It represents a failure on our part to find anything better than a barely humane and questionable remedy. To me at least, trying to see things from the patient's point of view, this latest "advance" of medical science appears as a disguised therapeutic retrogression of a most disturbing kind.—I am, etc.,

London, N.W.8.

H. C. SCOTT

### Babies in Hospital

SIR,—I am in complete agreement with Dr. Margaret Dunstan (Jan. 2, p. 131) in her opinion that under present conditions it is dangerous to admit infants into hospital. It is not uncommon to see an infant who has been admitted for some more or less trivial complaint recover from this and later, while still in hospital, develop D. and V., become dehydrated, and die from undiagnosed mastoiditis. Further, many infants during convalescence from a severe air-borne infection also develop D. and V., become dehydrated, and die from undiagnosed mastoiditis.

There are two main reasons for the occurrence of these catastrophes: (1) bottle-feeding while lying down; (2) nursing a sick infant on his back. In both cases in this position mastoiditis is invited by food, vomit, or infected mucus entering the Eustachian tube. Bottle-fed infants should never be fed lying down; while feeding they should always be held in the natural position by a nurse. An infant too young or too ill to sit up or turn over should always be nursed well propped up, and should be turned at frequent intervals, first on one side and then on the other, and never be allowed to lie on his back. If these two simple rules were universally adopted many infant lives would be saved.—I am, etc.,

Liverpool.

P. W. LEATHART.

### Sciatica

SIR,—I have read with great interest the contributions on sciatica in recent issues of the *Journal*. Would you kindly spare me a little space for a few general observations? It is generally known that sciatica is not a fatal disease, and that most persons who get it are cured in a longer or shorter time with the ordinary methods of treatment. Some few who are cured of the pain carry with them a slight paresis of the leg; others have intermittent bouts of discomfort in their extremity, though not frank pain. I have not heard or seen in 30 years of medical experience any sufferer from the complaint permanently disabled from following his avocation. I was present at the Annual Meeting of the B.M.A. when James Barr of Chicago read his paper on the prolapsed intervertebral disk and its operative treatment, wherein he mentioned that some cases did not even benefit from the operation, and that some others acquired a tolerance that is compatible with a nearly normal life without operation. At that time I formed the opinion that if I got sciatica due to a prolapsed disk I would certainly hesitate to undergo a serious operation with no certainty of cure, and would rather be content to carry on with a partial disability.

It has never been clear to me how the intervertebral disk prolapse occurs. When the semilunar cartilage of the knee

gets displaced it is always due to sudden trauma. In the disk prolapse no such cause is observable. Moreover, it is not known whether there are normal people with prolapsed disk who do not suffer from any inconvenience. The discovery of the prolapsed disk with sciatica does not negative the possibility of a prolapsed disk with no symptoms.

It is not my intention to put back the clock of surgical endeavour, but we should not forget that colectomy for bands, adhesions, etc., was in great vogue within living memory. It is admitted that sciatica has a psychological basis: in plain language it suits the patient to have sciatica. Is it unlikely that members of our profession sometimes fall into the same pit when advising a certain line of treatment for their patients?—I am, etc.,

Waterford.

A. J. D'ABREU.

### Just Suggestion?

SIR,—I have read with the greatest interest the recent correspondence upon the subject of "fibrositis," "sciatica," and "myositis." It would seem that not only are these misnomers but that all methods of treatment hitherto employed for the relief of this disease might well be abandoned without much disadvantage to the sufferer, since each and every one of the therapeutic measures adopted are fundamentally neither more nor less than a combination of auto- and hetero-genous suggestion.

Once this is admitted the sufferer can, with a clear conscience and without prejudice to his chances of recovery, put himself into the hands of the orthodox or unorthodox practitioner according to his predilection or fancy. The admirable letter by Dr. Gallop on suggestion makes entertaining or depressing reading according to one's humour at the moment. It sums up what I feel sure, often seems "the long and the short of it" to those of us who have had any considerable experience of general practice, especially when one allows a cynicism born of advancing years and length of service to colour one's mental outlook.

Recent letters in your correspondence columns seem to point to the inevitable conclusion that, with the very obvious exceptions of a few specifics, such as the employment of the sulphonamides and penicillin, all forms of therapeutics can be dismissed as empirical, continually being proved to be scientifically unsound, and therefore to be relegated to the limbo of the "magic" of the medicine man. Suggestion, suggestion! is that all that we practise? According to the pundits the balance of evidence would seem to have established this as an indisputable truth. Well, well, and Amen!

However, the real purpose of this letter is to ask a question which very intimately concerns my personal welfare. For many years now I have suffered from recurrent attacks of "fibrositis." I apologize for the use of so unscientific a word, but it is merely to use a term which will convey in the vernacular this painful disability. I have from time to time been "cured" by massage, ultra-violet and infra-red rays, short wave, Droitwich brine. When the exigencies of my work have allowed time for these indulgences, all these therapeutic measures seem to have contributed to the exorcism. Alternatively, when time for these treatments has not been available, "cure" has been spontaneous, unless perseverance with one's work, punctuated *sotto voce* by a wealth of bad language, can be regarded as a sound therapeutic measure. I have received much kindly advice from sympathetic colleagues, from the cheerful instruction to perform the impossible feat of swinging my lame and extremely painful leg over the back of a chair to the extraction of my few remaining teeth and the instalment of a utility set of dining-room furniture. When afflicted I have been physically incapable of carrying out the former, and even when at my worst have not yet adopted the latter, since my own experience, which I now find supported by one of the highest authorities, has convinced me of the fallacy of the focal sepsis theory in the vast majority of cases.

Meanwhile I continue to have attacks as well as long intervals, sometimes very many months, of complete freedom. Is my disease psychosomatic, and if so, what hope have I? Suggestion could obviously not be taken seriously or hope to succeed in my case.—I am, etc.,

Oxford.

J. FRANKLAND WEST.

### Deep Massage

SIR,—In these days of emphasis on rehabilitation by progressive exercises surgeons may lose sight of the fact that certain soft-tissue lesions, commonly met with at fracture and orthopaedic clinics, cannot be cured—or at best very slowly—by active movements alone. Masseuses should be urged to display their therapeutic powers and thus bring into prominence the essential nature of the services they can give in this part of their field. Surgeons in charge of these clinics are thus asked to co-operate by sending to their masseuse, with a request for deep friction to the site of the lesion, cases of non-specific tenosynovitis at the wrist and ankle; supraspinatus and patellar tendinitis; traumatic and rheumatic lesions of any part of the erector spinae muscle, of the deep lumbar fascia, and of the supraspinous ligaments; injury, whether recent or long-standing, to the internal lateral or coronary ligaments at the knee.

It is not generally realized quite how effective deep massage can be in mobilizing soft structures so placed that active movements alone achieve this end imperfectly or not at all. This fact leads me to request that masseuses should be given a chance to show how indispensable their manual work can be in the proper case. Though the conditions listed constitute only a small fraction of a masseuse's scope, they have been selected for their slow recovery under orthodox treatment and for the spectacular response that adequate friction regularly achieves.—I am, etc.,

London, W.1.

JAMES CYRIAN.

### Chemistry of Vitamin Therapy

SIR,—In your issue of Jan. 29 Dr. Griffith Evans refers to the Ministry of Health vitamin test scheme, suggesting that no steps were taken to estimate the vitamin sufficiency of the children tested. This is not correct, as in conjunction with, and with the approval of, the Ministry of Health every child in the scheme in Glossop was tested regarding his sufficiency or otherwise in vitamin C by the method mentioned by Dr. Evans, and in addition blood tests for vitamin C were carried out. Further, every child in the scheme was tested for vitamin A by the dark-adaptation test, etc. (the criterion of vitamin-A deficiency being that of Steven and Wald). An account of the work and of the findings was published in the *Journal* of Oct. 16, 1943 (p. 447), by Drs. Kohn, Milligan, and Wilkinson. It will be seen in this paper that in some instances the children having the vitamin capsules did significantly better than those who did not get them.—I am, etc.,

Glossop.

E. H. M. MILLIGAN.

### Plastics in Splint-making

SIR,—I was glad to see in your issue of Jan. 29 (p. 152) Mr. Campbell's article drawing attention to the value of perspex as a medium for making splints where it is desirable to combine lightness with strength. Undoubtedly this plastic has a great future in the field of splint-making, and I would like to record some simplifications in technique, which are not referred to by Mr. Campbell and which I have found in the course of six months' experimenting with the material.

1. *Softening by Heat.*—If a local kink is wanted it is best to heat the perspex in a bunsen burner; it then remains hot for some minutes, giving ample time for the required shaping. If a large sheet is wanted supple, this is best held over a wide gas-ring. When heated in water it does not stay malleable so long as when dry-heated.

2. *Cutting.*—When heated as above the material is cut as easily as pastry by strong hot scissors. Sawing it cold is a very laborious process and very injurious to the saw. The perforations for stitching webbing straps on can be produced by an electric drill on the cold material. If the strap is carried completely round the splint, very few stitch holes are needed, as compared with a strap on one side pulling directly on the stitches.

3. *Moulding.*—When the material has been heated one can mould it most accurately with one's hands if they are protected with a pair of asbestos gloves. Any metal tongs used on the material must be heated, for cold metal cracks the hot perspex. If moulded thus it is rarely necessary to prepare a plaster

model first, which is itself a laborious and fairly expensive process, and is particularly tricky for fingers and thumb, the very organs for which perspex is admirably adapted.

4. *Cooling.*—If quick cooling is desired, as when there is no cast on which to bandage the splint while hot, this can be readily induced by exposing the region involved to the cold blast of an electric hair-dryer. If it is cooled too rapidly the perspex becomes brittle, like very highly tempered steel.

I have produced dorsal cock-up splints for foot-drop and wrist-drop (with ring to sole or palm); also abdominal apron for poliomyelitis, and various types for paralysis of the intrinsic muscles of the hand. I am trying it for spines.—I am, etc.,

Bath.

M. FORRESTER-BROWN.

### Removal of Massive Calculus: Recovery

SIR,—The letter by Mr. J. Armstrong (Feb. 5, p. 200) on multiple vesical calculi recalls to my mind a massive single calculus which I removed from a Mesopotamian Arab in 1917. The victim was a well-known beggar who sat at the entrance to the native bazaar in Amara. He was unable to stand erect, and every few minutes crawled away to squeeze painfully a small quantity of urine from his bladder. I persuaded him to come into hospital, and with the help of the late Capt. J. M. Downie I removed a calculus, with the aid of midwifery forceps, which weighed 2 lb. 7½ oz.

According to local custom the patient's friends removed him from hospital on the day following operation, and carried him to their village some miles away in the marshes. His dressings were discarded, and the wound plastered with warm camel dung caught in a receptacle before reaching the ground. About three months later I saw a small crowd in the bazaar, and on investigation found a man exhibiting the stone at "an anna [penny] a peep." I asked him where he obtained it, and he startled me by pouring out profuse thanks for having cured him. His condition was so much improved that I thought he was an impostor until he threw aside his clothes and exposed a well-healed scar.—I am, etc.,

London, W.1.

MCNEILL LOVE.

### Tonsillectomy in Children

SIR,—For a long time now articles have appeared in various medical journals, generally backed by statistics, purporting to show that tonsil and adenoid removal in children is at the best useless and even may be harmful. That this opinion, even after many years, is held by a small minority is obvious and, I think, significant. In hospitals up and down the country laryngologists still struggle with nearly overwhelming lists of children for tonsillectomy, urged on by those watchful observers, the paediatrician, the general practitioner, and the school medical officer, who, in turn, are backed by the parents and the school teacher.

I have had the opportunity of observing the effects of this operation over a long period at various hospitals in London, including a large children's hospital, and I have always tried to be impartial in my judgment, both as to results and statistics. That the latter may sometimes unwittingly be fallacious I discovered when, before the war, I examined in a provincial centre over 500 reputed tonsillectomized children, and found that less than 17% had had their tonsils and adenoids adequately removed.

Regarding results, I have always found these to be excellent provided that the well-known criteria for operation were adhered to, and that the tonsils, all the tonsils, and nothing but the tonsils, were removed, and that the adenoids were removed without damage to the Eustachian cushions. It has been my observation that chronic ear and sinus infections are most frequently seen in children with unhealthy tonsils and adenoids, and that an essential factor in the successful treatment depends upon removing this tonsillar sepsis. In private practice, where there is more time to talk with the parents and doctors concerned, one hears in detail of the progress made. I have had parents who, vividly remembering the improvement made in other children after operation, have been disappointed and a little dubious when I have advised against tonsillectomy in another child of the family as unnecessary.

I wonder which camp would claim this case. Last spring I was asked to see a boy of 12 who a few years previously

had had a tonsil and adenoid operation. Subsequently he developed scarlet fever and a chronically discharging ear. On examination of the throat there were large tonsillar remains and much scar tissue. Cervical adenitis and bilateral antral infection were also present. The removal of the tonsillar remains has resulted in a dry ear, with a hearing loss measured audiometrically now trivial. The child has put on weight and the antral condition has now subsided.

I write this letter realizing that it is impossible for one person to cover adequately the ground of even one operation, and that to arrive at a balanced judgment results must be taken from many angles and from many observers.—I am, etc.

London, W.1.

E. CAREW-SIEM

### Cleansing Gas-contaminated Persons

SIR.—I see from your issue of Jan. 29 (p. 163) that my article on teaching "gas" by means of a miniature gas-post has brought forth a torrent of criticism. First I am accused of having made a glaring mistake in publishing a dangerous diagram, and I am told that I should have read the official handbooks. I can only reply by referring Cmdr Pitt Palmer to p. 89 of *A.R.P. Handbook*, No. 1 (2nd ed.), where he will see the eye douche in the same position. This also is the position it occupies in the latest circular issued by our local authority. I entirely agree with him that liquid gas in the eye must be removed at the very earliest moment and that it is best done with warm water, but warm water is not available immediately in an outer shed, nor are the conditions there suitable for eye douching at night.

Cmdr. Pitt Palmer quotes my words "not to instruct, but to show how instruction may be given." He then goes on to say that, according to the diagram, the patient must go through endless formalities with labels, string bags, etc. and eventually be undressed before his eyes are attended to. May I ask in which part of the diagram (which does not illustrate technique) is a patient shown passing through with contaminated eyes? Or can he quote one single word in the article which suggests that we practise as he asserts that we do? He remarks that the basis of all training is common sense; but he is not very generous in accrediting this virtue to others.

That the patient is taken to the eye-douching section immediately, and is undressed after his eyes have been attended to, is merely complying with the instructions given in *A.R.P. Handbook*, No. 2 (4th ed.), p. 12, which states: "The patient should be directed at once to the place where the eye douching is to be done, notwithstanding that this is a departure from normal procedure." That the patient should not be undressed first was clearly indicated, even in the amendment to the 3rd ed., p. 13, where the words "the casualty, who will have been undressed" were deleted. On the same page the following words were added: "Care should be taken to avoid, as far as possible, his coming into contact with persons who have removed their contaminated clothing," which suggests that the eye douching has been carried out indoors.

In reply to the sarcastic "eye douche (singular)," may I remind your correspondent of the obvious—i.e., that the miniature gas-post was for teaching only, and was never therefore intended for full practice, which is still given in a fully equipped gas-post. I am pleased to assure Cmdr. Pitt Palmer that we have a supply of antgas ointment at the "dirty" end of our gas-post. It was not considered necessary to mark small items of equipment on the diagram, which was intended to indicate solely the general lay-out of a gas-post.—I am, etc.,

Edinburgh.

POLLOK DONALD.

### Emulsions

SIR.—Dr. W. F. Cooper is to be congratulated on his letter of Jan. 29. Its implied criticism is applicable to every dermatologist, and indeed every physician who has the temerity to sign his name to a prescription. A moment's thought on Dr. Cooper's letter induces a realization of almost complete ignorance as to how medicament reaches tissue or bacteria, and of the physical rules governing such contact. Few of us consider how this last can be rendered more intimate. So far as I am aware there is no dermatologist to-day with the necessary mathematical or physicochemical knowledge to follow

up Dr. Cooper's "provocation"—a matter for regret. It is to be hoped that a physical chemist with an interest in medicine will some day arise to answer the demand.

Is it too much to hope that paraffin molle and aqua pura will be finally relegated to the realm of "inert" vehicles and replaced by co-operative rather than passive diluent?—I am, etc.

Manchester.

P. B. MUMFORD.

### Collaboration in Hospital

SIR.—The Medical Council of St. Bartholomew's Hospital recently celebrated the centenary of its formation. The resolution forwarded to the medical officers by the Governors in July, 1843, was as follows:

"That a Medical Council be formed to which may be referred matters relating to the Medical department of the Establishment, and to the Medical School.

That the Council do consist of the Physicians, the Surgeons, the Senior Assistant Physician, the Senior Assistant Surgeon, and a Secretary, to be appointed according to rotation from the four remaining Medical Officers, and that the Senior Member present at the commencement of Business do take the Chair.

That in the event of any of the said Physicians, Surgeons, Assistant Physicians, or Assistant Surgeons lecturing at, or being in any way connected with any other School than that of this Hospital, he, or they shall be disqualified from acting as Members of the Council.

That all business brought before the Council shall be decided by the majority present, except such matters as are to be submitted to the Treasurer, and Almoners, or Governors, when every Member of the Council be required to attend, and no decision of such Council shall be conclusive unless the majority acquiesce therein.

That in all the reports of proceedings submitted to the Treasurer, and Almoners, or the Governors, the names of the Members present shall be stated.

That all business referred for the consideration of the Council from the Governors be inserted in the summonses convening such Meeting."

This step was taken so that the treasurer and almoners might consult the hospital staff on matters of medical importance. In view of the present emphasis upon medical reorganization it was thought that the matter might be of interest to your readers.—I am, etc.

F. C. W. CAPPS,

St. Bartholomew's Hospital.

Hon. Secretary, Medical Council

### The Doctor's Vocation

SIR.—J. S. Fairbairn's death has been recorded with many appreciations of his life's work. The tone of these appreciations has brought to my mind the following excerpt from a letter of a father to his son:

"I have been thinking very anxiously over your letter. We must now decide what you are to be. There is indeed nothing I could more desire than to see you a good doctor; and a good doctor you will be if you are a good man working for the right reasons.

"There is no harder life than a doctor's; but so far as it is mere hard work it is not to be feared. What does not involve labour is not worth doing. But think of this: a doctor has to care for human life—he has suffering and disease to cure. The living look to him to save the dying and the dying look to him for life. You can remember from our experience of last year how much unnecessary pain a doctor's error of judgment may cause; and mother can tell you of many cases where an error of judgment has had more serious results—has caused loss of life. But we know also how much a doctor may do for a patient—Dr. Keith saved our dear Barbara; we shall never cease to be grateful to him for the kindness and skill which gave her back to us. And many a life he has so saved.

"Now do you know why I am saying this? To make you understand the grave responsibility of choosing such a profession—I would not have a son of mine enter it unless it were to do his duty in it; and his duty is to use all his energies and efforts to lighten the suffering and sorrow of man. What this means you cannot as yet fully know, but if you feel that you can be the best possible and do the noblest possible by being a doctor, then a doctor, so far as I can help you, you shall be. And I will stand no longer in the way of your practical chemistry.

"When you were a little child, I often thought how willingly I would consent to be nothing and do nothing in the world if I could

only make you a good man! And I feel so still—anxious only to see you one who could serve your God and your kind! If you do that, I shall be happy to be remembered only as your father. . . .”

The son was about to choose medicine as a career. The father was Andrew Martin Fairbairn and the son was J. S. Fairbairn. The letter was dated April 12, 1884, and was published in *The Life of Andrew Martin Fairbairn*.—I am, etc.,

Carmarthen.

J. R. E. JAMES.

### A Health Journal for the Layman

SIR,—I am perturbed by a certain class of literature on “health,” “hygiene,” “psychology,” “sex problems” which is in circulation in the form of magazines, booklets, correspondence courses, and the like. This type of publication does not usually come the way of practitioners, but those who took pains to look into it would be astonished at the extraordinary jargon which is hashed up and dished out for popular consumption. If there are people with a sincere desire for expert instruction, then it would not seem to be in their best interest that their need should be exploited by what may fairly be described as the pseudo-scientific press.

It is highly dubious whether the available material serves any worth-while social purpose; and there is no doubt that in some cases harm may result. For example, there are individuals who, acting on directions, persevere in douching the nose with irritating fluids for the treatment of a cold or to prevent further colds. As might be expected, what usually happens is to prolong the cold into a period of months with the danger of spread of inflammation into the Eustachian tubes. More ominous is the case of a young woman who, following a course of instructions to the letter, was resolute to rid herself of dreams by “sheer force of willing.” The disastrous effect on the mental state of such a devastating procedure can well be imagined. Some fantastic things are perpetrated under the guise of “psychological” drilling. I dare say that most practising doctors could mention similar incidents.

Cranks there will always be, but there are others with a genuine desire for knowledge and guidance, and the normal healthy-minded person would be the first to welcome clarification of topics relevant to the health of the individual and the social body. I venture to suggest that, in the light of the present conception of social medicine, the time is opportune to offer to the general public full facility for rational approach to authentic and up-to-date information and authoritative views. True, something is already being done: broadcasts by doctors, lectures on psychology, publication of pamphlets are steps in the same direction; but not everyone can listen to broadcast talks or attend lectures, and pamphlets may not get through to the populace. It may be that certain aspects of health education could be effectively presented in the form of a journal; there is something personal and vivid about a current periodical with familiar lay-out and features and that sense of news fresh from the print. And the art of attractive composition is not entirely foreign to medical writers. I suggest there would be scope for the right kind of health journal and at this would be a useful social asset.—I am, etc.,

Salford.

JOSEPH PARNES.

### Consultant and Specialist Services

SIR,—Certainly Mr. H. J. McCurrah (Jan. 29, p. 158) has reason for being perturbed about the totalitarian methods which are being employed to frame the future of consultants. As nine out of ten consultants in the United Kingdom are not attached to undergraduate teaching hospitals, it is difficult to understand why nine out of ten of the committee selected to meet the Minister of Health in connexion with the Beveridge scheme were drawn from the staffs of undergraduate teaching hospitals. Can it be that the Minister's primary consideration is the betterment of undergraduate teaching, which indeed is in need of reform; or, midst this oyster-like secrecy, are we to assume that for the present the welfare of the “herrenvolk” of consultants is the Minister's first concern? As time goes on, perhaps we may look forward to a plebiscite of the remaining nine-tenths of the consultants.—I am, etc.,

HAMILTON BAILEY.

## Obituary.

E. R. MORTON, M.D.TOR., F.R.C.S.ED.

News has been received of the death in retirement at Gullane, East Lothian, of Dr. E. Reginald Morton, who in former years was a leading radiologist in London, holding the post of medical officer in charge of the electrical department of the London Hospital and later that of radiologist to the West London Hospital.

Edward Reginald Morton, son of Edward D. Morton, M.B., was born in Barrie, Ontario, on Oct. 14, 1867. He graduated M.D., C.M. at the University of Toronto in 1890, and took the Scottish Triple qualification and the D.P.H. in the following year; in 1893 he became F.R.C.S.ED. Soon after graduation he accompanied Lord Brassey on the yacht *Sunbeam* as medical officer on a voyage to Australia and then for a short time assisted his father in practice. After the discovery of the x rays by Roentgen, Morton took a keen interest in the medical possibilities of the new rays and became one of the pioneers in this country. He was then in general practice at Taunton, experimenting with x rays in his spare time. His work soon attracted attention, and in 1904 he moved to London and was appointed to take charge of the electrical department of the London Hospital. In 1909 he gave up that post and became medical officer in charge of the x-ray department of the West London Hospital and lecturer in radiology at the West London Postgraduate College. During the last war he acted as radiologist to No. 2 London General Military Hospital, and after the armistice he visited Erlangen in Bavaria, where his friend Prof. Schrumph had been developing deep x-ray therapy during the war. On his return Reginald Morton introduced the new technique to this country. In 1922 he accepted an invitation to lecture on the subject in the U.S.A. and Canada. He made an extended tour of both countries and gave many lectures in Toronto, New York, Los Angeles, and other cities. On that tour he was accompanied by his old friend General Fotheringham, R.C.A.M.C.

Morton was a past-president of the Electrotherapeutic Section of the Royal Society of Medicine and a corresponding Fellow of the Academy of Medicine of Toronto and of the X-Ray Society of North America. He joined the R.M.A. in 1897, was secretary of the Section of Therapeutics in 1906, and president of the Electrical Section at the Annual Meeting of 1908. He published *Essentials of Medical Electricity and Radiology* in 1910, and five years later a *Textbook of Radiology*, which reached a second edition. In 1926 he retired to his summer home at Westbourne, Gullane, where he lived happily until his death on Jan. 21.

JOHN BARLOW, M.D., F.R.C.S., F.R.F.P.S.G.

Dr. John Barlow, whose death took place at his home in Callander on Dec. 27, 1943, was the oldest member of the medical profession of Glasgow. He was born in 1853 at Leigh, near Manchester. He studied medicine in Anderson's College, Glasgow, and at Glasgow and Edinburgh Universities, graduating M.B., C.M.ED. 1875, and M.D. 1879, having previously qualified M.R.C.S.Lond. in 1874. In 1881 he became F.R.F.P.S.Glas., and in 1885 F.R.C.S.Eng. He devoted himself in his early years to physiology, first as assistant to Prof. McKendrick in the University of Glasgow, then as the first Muirhead demonstrator in physiology in the Royal Infirmary School of Medicine, and later as professor of physiology in St. Mungo's College, into which was absorbed the Royal Infirmary Medical School. He lectured in physiology at the Royal Technical College of Glasgow, and was, in addition, a most acceptable lecturer to popular audiences. His training and intimate knowledge of physiology proved of great service when he began work in surgery, his real professional objective. In 1892 he was appointed visiting surgeon to the Royal Infirmary of Glasgow, and on retirement in 1913 was appointed honorary consulting surgeon.

Dr. Barlow took an active part in the work of the Royal Faculty of Physicians and Surgeons, as examiner and as a

member of council, and finally, from 1913 to 1915, as president. He was a fluent and telling teacher of both physiology and surgery, and, although making no claims in originality or in research, he did good solid work. Some of his contributions to these subjects were "Physiological Action of Ozonized Air," *Journal of Anatomy and Physiology*, "Saunders of Surgical Operations, 1883-1892," *Glasgow Medical Journal*, and "Intussusception in Infants treated by Abdominal Section," *Lancet*, 1899. Three members of his family became members of the medical profession; one of his daughters is the wife of Mr. George Mowat, surgeon to the Royal Infirmary, and is doing wartime work in the Eye Infirmary, Glasgow.

#### SIR JOHN RAMSAY, CBE, MS, FRACS

A Reuter message from Melbourne has announced the death of Sir John Ramsay, former president of the Tasmanian Branch of the British Medical Association, and for 14 years surgeon-superintendent of the Launceston General Hospital, Tasmania.

John Ramsay was born in Scotland on Dec. 26, 1872, son of John Ramsay and Margaret Thomson. In early life he went to Australia and studied medicine at Melbourne University, graduating M.B., B.S., and afterwards proceeding to the M.S. degree. He then made his home in Tasmania and became consulting surgeon to the public hospital at Launceston. During the last war he served with the rank of major as surgeon to the 12th Australian Hospital in Tasmania, and for his military services was created C.B.E. After his retirement from the post of surgeon-superintendent of the Launceston General Hospital he was elected consulting surgeon. Sir John Ramsay was one of the founders of the Royal Australasian College of Surgeons in 1926; he served for six years (1920-6) as president of the Tasmanian Branch of the B.M.A., and had been elected a member of the Association as long ago as 1894. He was created a knight in 1939, his name appearing in the New Year Honours List for services to surgery in the Commonwealth of Australia. He had been a keen cricketer in early days, kept up his interest in golf, and was the first president of the Rotary Club of Launceston. He married Ella Elizabeth Pegus Dudley of London, and had three sons and two daughters.

#### MOHAMMAD HUSNAIN, O.B.E., M.B., F.R.C.S. (Ed)

Prof. Mohammad Husnain, head of the department of ophthalmology at the Prince of Wales Medical College, Patna, died suddenly at Patna on Sept. 10, 1943, in his forty-seventh year. To those who knew him well and had had the privilege of working with him the news of his death brought a deep sense of personal loss. In him the Medical College lost a very able teacher and the medical profession lost an eminent ophthalmic surgeon.

Prof. Husnain was educated at the Calcutta Medical College, and obtained the M.B. degree of Calcutta University in 1921. He joined the Provincial Medical Service in Bihar the same year and was posted to the public health department. In 1925 he was appointed house-surgeon in the department of eye, ear, nose, and throat of the Medical College Hospital at Patna, and later worked as house-surgeon in the general surgical wards in the same institution. In 1929 he proceeded to Europe, and obtained the diplomas of D.L.O. (London) and D.O.M.S. (London). In 1930 he was admitted as a Fellow of the Royal College of Surgeons of Edinburgh. Later he worked as house-surgeon at the Birmingham and Midland Ear and Throat Hospital for 8 months. On his return to India in 1931 he was appointed lecturer in ophthalmology at the P.W. Medical College, Patna, and in 1935 he was made professor in the subject. He was a Fellow of the Patna University and a member of the Faculty of Medicine and Board of Studies in Medicine. He was a member of the Bihar Branch of the British Medical Association and was president of the branch in the year 1942. He was made an O.B.E. in the New Year Honours List of 1943. He leaves behind a widow and a large circle of friends and admirers to mourn his loss.

The Bihar Branch of the B.M.A. has passed a resolution placing on record its deep sense of sorrow at the premature death of Prof. Husnain, a member of the Association since the inception of the Branch and one of its ex-presidents.

News has been received of the death at Cannes in October of Dr. ARCHIBALD ADAM WARDEN, from whom only occasional messages had come through since the fall of France. Born in Edinburgh on May 11, 1869, Dr. Warden was educated at Rossall School and Glasgow University, where he graduated M.A. in 1889, M.B., C.M. in 1893, and M.D. in 1898. After serving as resident in the Western Infirmary, Glasgow, under Sir Hector Cameron and Dr. Samson Gemmell he went to the Hertford British Hospital in Paris as R.M.O. and received the diploma of Docteur en Médecine de la Faculté de Paris in 1899. He then started private practice in that city and became physician to the British and the American Hospitals, and soon secured a large clientele. He extended his work to Cannes, and some 20 years ago left Paris to devote himself to medical practice in Cannes and its neighbourhood. During the last war he served with the British Forces at a hospital at Dieppe. Dr. Warden had been a well-known lawn-tennis player, both as a student and afterwards in France, where he won the French doubles championship with W. S. M. Vines in 1896; he was also a very early motorist and an enthusiast for the open-air life in summer and winter. He was for some years an occasional contributor to the *Lancet* and the *B.M.J.*, and at the time of his death was known to be working on *The Reminiscences of a Scots Doctor in France*. Dr. Warden's visits to Scotland were rather infrequent, as he preferred that his British friends should spend holidays with him in the South of France; he attended the British Medical Association Meeting in Glasgow in 1922, when Sir William Macewen was President. His wife is a daughter of the late Prof. McKendrick of the Chair of Physiology in Glasgow University. He is survived also by a daughter and two sons, one of whom is a prisoner of war in Japan.

The death occurred on Oct. 26, 1943, of Dr. HUGH JOHN O'PREY at his home in Antrim Road, Belfast. Born at Portaferry, Co. Down, in 1885, he graduated M.B., B.Ch., B.A.O. of the Queen's University of Belfast in 1918. After a year as house-surgeon in the Mater Infirmorum Hospital, Belfast, he was clinical assistant in the Samaritan Hospital for Women, London. For more than twenty years Dr. O'Prey carried on an extensive family practice and established his reputation as a skilful and resourceful obstetrician. His fatal illness became apparent some months ago, and he faced it's inevitable end with faith and courage. He is survived by his wife and two children.

News has reached this country of the death of Dr. ROBERT DONALD FLETCHER on Dec. 13, 1943, from coronary occlusion, in Hollywood, Florida. Dr. Fletcher was born in Edinburgh on July 16, 1878, and was educated at Watson's College, Edinburgh, and graduated M.D. at the University of Manitoba in 1903. He practised medicine in Winnipeg and was professor of urology at the University of Manitoba, from which he retired about 1936. He was a member of the British and Canadian Medical Associations and of a number of American urological societies. He is survived by his wife and three daughters.

We regret to announce the death on Jan. 26 at his home at Skinburness, Carlisle, of Dr. JOHN WELSH SMITH. He studied medicine at the University of Edinburgh and graduated M.B., C.M. in 1890; thereafter for 45 years he gave faithful service as medical officer to the parish of Dunscore, Dumfriesshire. Dr. Smith joined the British Medical Association in 1894, and was chairman of the Dumfries and Galloway Division in 1933-4 and president of the Border Counties Branch in 1936-7. He was very well known socially and professionally in the South of Scotland, and his election to these two offices in the B.M.A. gave proof of the esteem and regard in which he was held by his colleagues. Possessed of many attainments, he travelled on sea for several years before settling down in general practice at Dunscore. He took a keen interest in languages, including ancient Greek and Arabic, and he also spoke a number of modern languages quite fluently, including French, Russian, and German.

Dr. TOM STANSFIELD, honorary consulting physician to the Royal Berkshire Hospital, Reading, died on Jan. 25, aged 57. A student of Guy's Hospital, he graduated M.B., B.S. (London) in 1910 and then became house-surgeon to the Dorset County Hospital, Dorchester. During the last war he served with the rank of temporary captain, R.A.M.C., and after returning to civil life in 1919 was appointed physician and medical officer in charge of the special eye department at the Royal Berks Hospital. Dr. Stansfield joined the British Medical Association in 1917, was chairman of the Reading Division in 1936, and had been president of the Berks, Bucks, and Oxford Branch. Dr. Tom Stansfield (writes S. C. A.) spent most of his life in Reading, where his father was in practice. After leaving Guy's he worked for a short time in Birmingham and Taunton, and

then, on the outbreak of war, volunteered for the R.A.M.C., with whom he spent the next four years. He was wounded in the head. After the war he settled with his father in Reading and continued the practice alone after his father's death. He was never in robust health, and was unable to carry on his work at all since last May. Two years ago he resigned his position as assistant physician at the Royal Berkshire Hospital, a position he had held for 21 years. He was always a very active member of all medical organizations in the district. He was honorary librarian to the Reading Pathological Society for many years. He was a past-chairman of the Reading Division as well as the Berks, Bucks, and Oxon Branch of the B.M.A. For twelve years he was chairman of the Reading Insurance Committee and for a longer period he served the profession as chairman of the Reading Panel Committee and the Borough of Reading Medical Society. He was a valuable member of the Reading Medical War Committee. From his father, who was the greatest authority on British ferns in his time, he inherited a great love of natural history. Some years ago he was elected a Fellow of the Linnaean Society. He also acted as secretary of the Pteridological Society. Dr. Stansfield will be sadly missed by his colleagues in Reading.

Dr. ARVID LUDVIG KELLGREN, who died in London on Jan. 31, was born at Alingsås in Sweden on April 25, 1856. He decided to follow in the footsteps of his elder brother, the well-known medical gymnast Henrik Kellgren, and graduated at the Royal Central Gymnastic Institute of Stockholm during 1879. He then determined to study medicine and went to Edinburgh, where he graduated as M.B., Ch.B. in 1886. After this he devoted himself entirely to the practice of medical gymnastics according to the methods of Ling and his brother Henrik. During 1888, for his successful treatment of the Empress of Austria, he became the recipient of the Austrian Imperial Order of the Iron Crown. During the same year he demonstrated the Ling-Kellgren methods at the Naval Hospital at Pola, and an extensive paper on them was published in the *Stat. Sanber. d. K.K. Kriegsmarine* for 1888. This communication formed the basis of his thesis which was accepted with commendation for his graduation as M.D. in 1890, under the title of "The Technique of Ling's System of Manual Treatment." These two works contained the first detailed description of Henrik Kellgren's so-called "nerve frictions and vibrations," and the thesis mentioned was translated into French, German, and Italian. Kellgren made a number of researches on the physiological effects of massage and vibrations which were duly published in *Clin. franç.*, 1894, *C. r. Soc. Biol.*, 1895, and *Arch. de Physiol.*, 1896. Further researches, made in conjunction with Dr. Carlo Colombo of Rome, were issued in book-form during 1897 under the title of *Absorption of Exudations under the Influence of Massage*. A paper with practical demonstrations on new movements in manual treatment was read by him before the International Congress of Medicine at Rome in 1894. At the hands of the King of Sweden he received the decorations of Knight Commander of the Vasa and Knight Commander of the North Star.

Dr. MAYNARD HORNE, who was born on March 30, 1870, and died at Rickmansworth on Feb. 7, 1944, was educated at Haileybury, Trinity College, Cambridge, and St. George's Hospital Medical School. He was for a time in general practice, and served for many years as physician to the Margaret Street Hospital for Consumption; but most of his professional career was devoted to the specialty of anaesthetics. Having qualified M.R.C.S., L.R.C.P. in 1899, and taken the M.B., B.Ch. at Cambridge in 1901, he held house appointments at his own hospital, which he served also later as anaesthetist, and where he was made consulting anaesthetist on his retirement. He had also been anaesthetist to the Hospital for Women, Soho Square, the Seamen's Hospital, Greenwich, and the National Orthopaedic Hospital. He had an aptitude, almost a genius, for friendship—Polonius would have liked to know him. He married, while still a student, Lillie, daughter of the late Mr. T. Pearson, and had one son and two daughters. He was a highly expert and enthusiastic lawn tennis player; and when already a grandfather could often astonish men many years younger by his activity and the high standard of his play. During the first world war he served as a captain in the R.A.M.C.(T.) at base hospitals in France. He was a colleague whose friends will sadly miss his cheery personality.

The following appreciation of Lieut.-Col. DONALD UVEDALE OWEN, whose death on active service was announced in the *Journal* of Jan. 8, has been received from a Liverpool colleague: Donald Owen had been away from us right from the beginning of the war, called up for service as a Territorial officer. Before long he was in charge of a general hospital, which he later took to the Middle East. His experience in tropical diseases

led to specialized work in that field, and last year he was mentioned in dispatches for distinguished services. Then came the news of his illness—how serious many of us hardly realized until we heard that on his way home he had to be put off the ship and left behind in South Africa, there to have weekly blood transfusions for an aplastic anaemia. Donald was a first-rate clinician, all the sounder for the time he had spent with Warrington Yorke as clinical pathologist to the Liverpool School of Tropical Medicine. With his election to the staff of the Royal Southern Hospital, he transferred his energies to general medicine, and after a few years there he became assistant physician to the Royal Infirmary. Among various papers which he published two of them stand out as illustrating his quality—a careful study of urobilinuria, done in Yorke's department, and a sensible, illuminating re-examination of Pancoast's "superior sulcus tumour," in collaboration with Hewer and Whittaker. His patients, private or "hospital," were always impressed by the apparently endless time and care which he was ready to give them—even though it often meant that he was late for the next consultation; they used to say of him that he never seemed to be in a hurry to get away from them. He enjoyed his medical work, and he enjoyed life. He was a foundation member, and the first president, of the Innominate Club, the most junior of the medico-literary clubs in Liverpool. He was a keen tennis player, and he and a gynaecological colleague made up a doubles pair for Mersey Bowmen. Dancing, parties, students' dinners, all sorts of human contacts, he enjoyed them all, and in so doing made them pleasant for other people and especially for his friends. Good-natured, tolerant, and friendly, he nevertheless held firm and shrewd views. Had he come back to us safe and sound he would have been a tower of strength in the changing world of medicine which is upon us.

Dr. John Cahill writes: It is perhaps permissible for one who was closely associated with the late Prof. W. M. FALLON in his student days in Galway to pay a personal tribute to his memory. At that time, when he laid the foundations of his career, I could not help noticing his eager mind and the ease with which he combined interest in politics with interest in physiology. The event was to prove that he also possessed a still more valuable asset—the uncommon gift of vision—which enabled him to plan his career wisely from the beginning. Even a man of great ability—e.g., Wolsey—may lack this gift; of most of us, the words of Seneca ring true eternally—*Ignoranti quem portam petet, nullus sinus ventus est* (When a man does not know which harbour he seeks, no wind is the right wind). Years later, we spent a jolly afternoon together on the upper reaches of the Thames. He had just completed a course of study abroad and was full of ideas, full of enthusiasm. I never saw him again.

A correspondent writes: Medicine has lost a personality and a pioneer by the passing of HERBERT NOTT at Guildford on Feb. 2. After many years in practice at Long Sutton, near Birkenhead, Nott fell ill and was restored to health by colonic lavage with potassium permanganate. His interest in the treatment was stimulated and he used it extensively in a large practice. The success which followed led to the co-operation of several medical men, and in July, 1926, he published a paper in the *British Medical Journal* on thyroid and manganese in acute pneumonia. He went to live at Guildford and devoted his time to specialization in this treatment, and finally his book *Thyroid and Manganese in Treatment* was published. His implicit belief in the value of thyroid and manganese convinced a considerable number of medical men, but the lack of interest and even active opposition displayed by a section of the profession, including the Medical Research Council, were always a source of disappointment to him, and to the last he fought and strove to gain that general recognition for his technique which would allow humanity to reap the full benefit therefrom. Those who knew Herbert Nott will remember him as a good companion, a fine talker, and a firm friend, but he was a tough antagonist who did not easily tolerate criticism which was not based on practical experience, and his discoveries have not yet been sufficiently appreciated. Now that the value of trace elements such as manganese, zinc, and cobalt is beginning to be recognized and the all-important part played by the liver is becoming more and more apparent, it is probable that his pioneer work on these subjects will receive a far greater recognition from future generations in medicine than it has in the past.

The following well-known medical man has died abroad: Dr. LEO BUEGER, professor of urologic surgery at the New York Polyclinic Medical School, who gave his name to thrombo-angiitis obliterans in 1908, and was author of *Circulatory Disturbances of the Extremities*, aged 64.

## Medico-Legal

### USE OF A MEDICAL ASSESSOR

Many county courts have for long followed a practice in workmen's compensation cases by which the medical assessor examines the workman and reports his opinion to the arbitrator (the judge). The House of Lords has now ruled that this practice is wrong.<sup>1</sup>

A workman was ruptured at work and received compensation for total incapacity. He underwent an operation, but this was not completely successful. A few years later the employers required him to undergo a further operation. He refused, and they applied to the county court for a review or termination of the weekly payments on the grounds that his refusal was unreasonable. Sir Gerald Hulse, K.C., the arbitrator, was assisted by Dr. W. A. Broad as medical assessor. The employers called three doctors, who said that the operation was advisable and could be successful. The workman called two other doctors, who said the operation would be positively injurious to the man's nervous condition. At that his previous operation had left him with a neurosis. The arbitrator said that the medical assessor would like to examine the workman. This examination took place in private out of court and when the hearing was resumed the arbitrator intimated that the medical assessor's view was in favour of the proposed operation. After further argument from counsel he gave judgment for the firm, saying that he thought he was entitled to rely upon the advice of the medical assessor, who took the view that the operation would have no effect upon the workman's (nervous) condition. It was not dangerous, and he held the workman's refusal to have been unreasonable. He accordingly ordered that all payments should be suspended. The workman appealed unsuccessfully to the Court of Appeal and then to the House of Lords. The Lord Chancellor, Viscount Simon, pointed out that, as was held by their lordships recently,<sup>2</sup> the question of reasonableness is not to be determined by considering whether the best medical opinion would think the operation advisable or safe, but whether the workman, having regard to all the circumstances, including the advice of his own doctor, was unreasonable in refusing it. In other words, the court must consider the mind of the workman rather than the medical facts. The House, however, had another and wholly distinct reason for allowing the workman's appeal: that the arbitrator had wrongly allowed himself to be influenced by the medical assessor's advice. An arbitrator may submit to a medical referee for report any matter which arises in the arbitration, but whenever a referee examines a workman he must make a written report or certificate which is available to both parties. A medical assessor, said the Lord Chancellor, is one of the panel of medical referees, but that does not oblige the workman to submit himself for examination, and cannot constitute the assessor an unsworn witness who cannot be cross-examined and whose testimony need not be fully stated to the parties. The assessor is an expert whom the arbitrator may consult on the effect and meaning of technical evidence; he may in proper cases suggest to the arbitrator questions to put to an expert witness, and the arbitrator may ask him what inferences may properly be drawn from proved facts, or the extent of the difference between apparently contradictory conclusions of experts. Their lordships have now ruled that it is not part of his functions to conduct a personal examination of the workman, or to report to the arbitrator the effect of the examination and his deductions from it. The Lord Chancellor added that the arbitrator may, when faced with a conflict of medical evidence, submit the medical issue to the assessor as a referee, but then the report will be in writing and available to the parties. The medical referee is not, of course, exposed to cross-examination.

### CONSCIENTIOUS OBJECTION BY A HŌMEOPATH

The High Court dealt in January with an unusual appeal<sup>3</sup>: by a practitioner of homoeopathy against an order to serve as a junior medical officer, on the ground that he had a conscientious objection to giving "allopathic" treatment. Dr. Arthur George Davies of Cardiff was directed by a national service officer under Defence Regulation 58A to perform services in the United Kingdom as a junior medical officer at the Park Hospital, Wellingborough, for a period of six months. He failed to comply with the direction and was prosecuted before the stipendiary magistrate. At the hearing it was proved or admitted that he had a conscientious objection to giving "allopathic" treatment and that he would be required to do so. He was convicted of a breach of the regulations and fined £5 and £10 costs. He appealed, and the magistrate stated a case for the Divisional Court. Dr. Davies contended there that the

national service officer had not acted in good faith in directing him to perform services which the officer knew that he had a conscientious objection to giving, he having expressed his readiness to perform medical services on homoeopathic lines; he also pleaded that, being a homoeopath, he was incapable of performing the services he was directed to perform. The Ministry contended that the officer had acted in good faith and that a conscientious objection by the doctor was not a relevant matter of defence.

Mr. Justice Humphreys, giving the judgment of the court, said that while he had every sympathy for anyone called on to do anything that was in direct conflict with his convictions and beliefs, the decision of the magistrate was right. The court had to decide whether the officer's direction was lawfully given, and was bound to approach the case on the basis that he was a fair-minded person. It was for the officer to make up his mind whether a person called on to perform certain duties was "capable of performing" them. In the court's opinion the direction complained of was properly given and the doctor was a person capable of performing the duties required of him. His appeal was therefore dismissed.

By Regulation 58A any national service officer may direct any person in Great Britain to perform such services as may be specified by or described in the direction, being services which that person is, in the opinion of the officer, capable of performing. There is no appeal against a direction given by the officer, and conscientious objection is only recognized in connexion with service in the armed Forces. Dr. Davies's case was therefore not contemplated by those who framed the regulation. A question that comes to mind is: What have other homoeopathic practitioners done in similar circumstances? Without knowing the facts it is hardly proper to comment on the case.

## The Services

Capt. P. A. Forsyth, R.A.M.C., repatriated prisoner of war, has been mentioned in dispatches in recognition of gallant and distinguished services in the field before his capture.

The *London Gazette* has announced the appointment as M.B.E. (Military Division) of Capt. (temp. Major) W. E. Tucker and Capt. A. D. Aveling, R.A.M.C., repatriated prisoners of war, in recognition of gallant and distinguished services during and before captivity; and also of Temp. Surg. Lieut. J. H. L. Ferguson, R.N.V.R., for gallantry and great skill in rescuing and caring for wounded survivors from H.M.S. *Croimart*.

### CASUALTIES IN THE MEDICAL SERVICES

*Previously reported missing at sea, now presumed to have lost his life.*—Lieut. R. A. Palmer, R.A.M.C.

*Missing, presumed killed.*—Temp. Surg. Lieut. P. G. Jeffries, R.N.V.R.

*Wounded.*—Temp. Surg. Lieut. J. C. Bulstrode, R.N.V.R.

### DEATHS IN THE SERVICES

Col. CHARLES EDWARD HARRISON, C.M.G., C.V.O., A.M.S., died on Jan. 25 at Redhill while in his 92nd year. He was the son of John Harrison, who was born in July, 1787, so the two lives span the remarkably long period of 157 years. The father, John Harrison, was appointed assistant surgeon to the First Foot Guards in 1809 and served during that year in the ill-fated Walcheren Expedition, and subsequently in the Peninsular War in 1811-13, in Holland in 1814, and at the Battle of Waterloo in 1815. In 1824 he was battalion surgeon, Grenadier Guards, and only retired in 1840. His distinguished son, Col. Charles Edward Harrison, was born in 1852 and was educated at Wellington College and St. Bartholomew's Hospital; he passed the London M.B. with honours in 1876 and took the F.R.C.S.Eng. in 1878, having first qualified as M.R.C.S. and L.S.A. in 1874. He entered the Army in the same year as surgeon to the Grenadier Guards, like his father just fifty years earlier. He rose to be surgeon-major in the same famous corps in 1885, was promoted to the now long-extinct rank of brigadier surgeon lieutenant-colonel, Brigade of Foot Guards, in 1891, and to brevet colonel in 1907. In the year of his retirement, 1909, he was awarded the C.V.O. His war service included the Battle of Tel-el-Kebir in Egypt in 1882 (medal with clasp and star) and a period in France during the last war in 1914-15, when, in addition to medals, he was given the C.M.G. During his long service he also held the important posts of charge of the Queen Alexandra Military Hospital, the 1st London General Hospital, and was Assistant Director of Medical Services; he was appointed Hon. Surgeon to King Edward VII. His energies after his retirement from active service included command of a convalescent hospital in 1916, work in the Ministry

<sup>1</sup> Richardson v. Redpath Brown and Co., Ltd., (1943) 1 All E.R., 110.

<sup>2</sup> Steele v. Robert George and Co., 1942) A.C., 497.

<sup>3</sup> Times, Jan. 13, 1944.

of National Service in 1918, and in the Territorial Force Reserve in 1918-23. It will be long before the Army medical record of himself and his father is equalled. The funeral took place on Jan. 28 at Redhill with full military honours. Major-Gen. O. W. McSheehy, represented the Director-General, Army Medical Services, and the Grenadier Guards sent an unarmed escort of pall-bearers with buglers who sounded the Reveille and Last Post.

## Medical Notes in Parliament

### Consultant and Specialist Services

Sir DOUGLAS HACKING inquired on Feb. 3 whether the Minister of Health had considered the letter about consultant and specialist services appearing in the *British Medical Journal* and the *Lancet* of Jan. 15, signed by the Presidents of the three Royal Colleges, which stated that these colleges were at his request making a survey of the present availability of consultants and specialists. Mr. WILLINK said he had considered this letter. Surveys of the hospital services had been in progress throughout the country for some months. Their aim was to assist in producing plans for the co-ordination of those services after the war by ascertaining the supply of and probable demand for hospital facilities, and by making recommendations for any necessary extensions and improvements. At an early stage of these inquiries it became clear that a useful purpose would be served by the initiation of similar inquiries in England and Wales into the supply and distribution of consultants and specialists and the probable demand for them in a comprehensive post-war hospital and consultant service. Arrangements were accordingly made with the Presidents of the three Royal Colleges for a survey to be made of the existing consultant and specialist services to ascertain whether there was a surplus or shortage in any area and whether redistribution would be desirable in any post-war hospital service. The Royal Colleges had established a Central Medical Academic Council, including representatives of the universities, to perform the necessary work at the centre, and area committees based on the universities to undertake the collection of information and preparation of lists locally. Mr. Brown had invited the vice-chancellors of the universities to act as chairmen of these area committees. It was hoped that this survey would make available for the first time information about the numbers and types of consultants and specialists in the country. Information was already to hand about specialists in the Services. Misunderstanding appeared to have arisen owing to the fact that to arrive at the numbers and types of consultants and specialists it was necessary to draw up lists of names. Mr. Willink said he was glad of the opportunity to assure the profession, and especially its members on war service at home or abroad, that such lists would be treated as strictly confidential. They would not be used as a test for eligibility for appointment as consultant or specialist in any comprehensive post-war hospital service. If, at a later date, it was thought desirable that consultant and specialist appointments should be restricted to persons qualified in some particular manner and enrolled in a list for the purpose, it would be necessary to provide for the establishment of a register on a statutory basis in a manner approved by Parliament.

### Post-war Housing

A debate on post-war housing took place in the House of Lords on Feb. 8 on a question by Lord ADDISON to the Minister of Works. Lord Addison asked what steps the Government was taking to meet requirements in regard to plans, designs, and costs and to alternative methods and materials.

Lord PORTAL said that on all housing matters he was working in complete accord with the Minister of Health, whose Department dealt with the local authorities, and also with the Secretary of State for Scotland. The Ministry of Reconstruction and the whole Government were alive to the vital necessity for getting on with the question of housing at the right moment, for it was largely a matter of timing in view of the fact that the war effort was still demanding nearly all the available labour and materials in the country. The limit of expenditure on repairs to war-damaged and other houses was recently raised from £100 to £500. Privately owned houses would participate in this, and the instructions to licensing officers had been adjusted accordingly. Local authorities should be able to secure the carrying out of the great proportion of these repairs, and the back of them should be broken by the end of the year. If that could be done, an awkward job would be out of the way. The Government had decided that in the late spring and early summer arrangements would be made for the use by local authorities of plant and machinery, as these

became available from airfield construction, for the preparation of housing sites sufficient for the maximum number of houses that could be built during the first two years after the war. Sites would be settled and approved between the local authorities and the Minister of Health. The Ministry of Works was putting up a number of houses to demonstrate the use of different materials in permanent house construction, and to ascertain the costs. The question of the suitability of the houses rested with the Ministry of Health. Experiments were being made in the conversion of wartime hostels into temporary houses. The Government had gone a considerable way in getting out plans for a type of temporary prefabricated house. In considering prefabrication on a large scale, the questions of materials and the capacity available for their manufacture were vital if it was to be started before the war was over. The first prototype (made by hand) would be ready at the end of April when it would be shown to the Minister of Health, the Secretary of State for Scotland, and others interested in the matter. To avoid these temporary houses remaining in existence as they did after the last war, the Government had decided that, if approved, they should be publicly owned and licensed for a period. The Ministry of Works was also exploring with certain local authorities the extent to which it would be economic and practicable to convert large houses in urban districts into comfortable flats. One of the most effective ways of securing efficiency and economy in houses would be by far greater standardization of essential parts than hitherto: already a degree of success in standardization had been achieved. For instance, the various sizes of metal windows had been reduced by about 80% to three basic types which could be produced in 20 varieties. The types of baths had been reduced from 40 to 5, and water heaters, tanks, and cisterns from 270 to 100. Other items were also being dealt with along these lines. They would try to give the people houses to live in at rents which they could afford to pay. Steps were being taken to ensure the supply of all materials required for post-war building. The report of the Mission which went to America was issued on Feb. 7, and would be of great value. The report of Sir George Burt's interdepartmental committee would, he hoped, be published next month. With regard to the post-war work, the Ministry was fully alive to what the ex-Service man wanted, and it would not be the fault of the various Departments concerned if they did not give him what he required.

**School Meals in Scotland.**—On Jan. 18 Mr. JOHNSTON informed Mr. Thomas Henderson that for October, 1943, the number of children receiving meals (dinners or lunches) in schools in Scotland was 159,364, representing 21.2% of the number on the rolls, compared with 141,630, or 18.8%, in June, 1943. The number receiving milk was 513,502, representing 67.6% of the numbers on the rolls, compared with 520,124, or 68.5%, in June, 1943.

**Infant Mortality in Scotland.**—On Feb. 8 Mr. JOHNSTON informed Mr. T. Henderson that the five counties and large burghs respectively in Scotland with the highest death rates among children between one and 12 months in 1941 were: counties: Selkirk, Ayr, Kincardine, Dumbaron, and Caithness; large burghs: Port Glasgow, Dumbaron, Coatbridge, Glasgow, and Hamilton.

**Calcium in Bread.**—On Feb. 8 Sir E. GRAHAM-LITTLE asked the Minister of Food whether, in view of the recent demonstration, details of which had been submitted to him, before a scientific society, that the added calcium was due to a misconception, if, as the increased consumption of calcium salts raised the blood pressure from which condition every fourth person of late middle age died, he would institute an inquiry on the subject independent of the Medical Research Council, and, until the findings of this inquiry were available, stop addition of calcium to bread. Col. LEWIS said he was not aware of the demonstration to which Sir E. Graham-Little referred. He was advised on the best authority that the small amount of calcium now added to bread was beneficial for the continued good health of the nation and had not the effects which the question would seem to imply. The answer to the second part of the question was "No, sir."

### Notes in Brief

The Disabled Persons (Employment) Bill, which has passed the House of Commons, was read a first time in the House of Lords on Feb. 8.

## Universities and Colleges

### UNIVERSITY OF CAMBRIDGE

At a Congregation held on Feb. 5 the degrees of M.B.; B.Chir. were conferred by proxy upon J. W. Evans, M. P. Durham, L. L. Bromley, B. W. Rhodes.

During the month of January titles of the degrees of M.B., B.Chir. were conferred on M. K. E. Reaney of Gorton College.

# MERSALYL B.D.H.

*The Standard Mercurial Diuretic*

Mersalyl B.D.H. complies with the pharmacopoeial standards defined in the First and Fourth Addenda to the B.P. 1932 for Mersalyl B.P. and Injection of Mersalyl B.P. respectively; it may be employed in the relief of a wide range of oedematous conditions.

The most satisfactory uses of Mersalyl B.D.H. are probably in cases of minimum renal insufficiency such as oedema of cardiac decompensation or indeterminate origin and in nephrosis and polyserositis. Certain cases of local oedema following fractures also respond satisfactorily.

Mersalyl B.D.H. is normally administered intramuscularly (Inj. Mersalyl. B.P.). Mersalyl B.D.H. in tablets (containing mersalyl 0.08 grm. and caffeine 0.04 grm.) or in suppositories (containing mersalyl 0.4 grm. and theophylline 0.2 grm.) may be given to augment the effect of Mersalyl B.D.H. by intramuscular injection.

*Details of dosage and other relevant information will be gladly supplied on request*

## ASCABIOL<sup>®</sup>

TRADE MARK

brand of benzyl benzoate emulsion  
for the treatment of  
scabies

A single application of benzyl benzoate emulsion, provided it is thorough, will usually cure a case of scabies. The chief advantage of benzyl benzoate over some other sarcopticidal agents is the rarity of dermatitis following its use and recently the formula of 'Ascabiol' has been modified so that skin irritation following its use is minimal.

Recent clinical work indicates that this pre-

paration is effective also as a pediculicidal agent. A pamphlet describing life history of *Sarcoptes scabiei*, the properties of different sarcopticidal agents and the technique of the treatment of scabies will be sent on request. Pads of instruction cards for patients are also available. 'Ascabiol' brand of benzyl benzoate emulsion is supplied as follows :—

Bottles of 4 ozs. Bottles of 80 ozs.

Manufactured by  
**MAY & BAKER LIMITED**

Distributors  
**PHARMACEUTICAL SPECIALITIES (MAY & BAKER) LIMITED, DAGENHAM**

## Neurasthenia or Hypovitaminosis B<sub>1</sub>?

Many clinical manifestations, previously of doubtful ætiology, have been shown by modern vitamin research to be symptoms of hypovitaminosis. This applies notably to that protean group of symptoms the presence of which has so often led to the somewhat facile diagnosis, neurasthenia.

### RESPONSE TO VITAMIN THERAPY

The classical treatment of neurasthenia included rest in bed, reassurance and an abundant well-balanced diet. But, as one authority has aptly said, when cure resulted it was not the rest or the reassurance that effected it—it was the food. More accurately, in many cases it was doubtless the

Loss of appetite, ready mental and physical fatigue, anæmia, digestive disturbances, more or less vague aches and pains, and emotional instability—all these and other states which have been freely included in the picture of neurasthenia are now recognized as occurring in the presence of hypovitaminosis B.

### NATURAL SOURCE OF THE B COMPLEX

That a sub-standard level of vitamin B<sub>1</sub> is common is readily understandable, since the margin between average intake and physiological requirement of the vitamin is slim, and since the vitamin is not stored to any appreciable extent in the body.

A particularly convenient and effective means of ensuring that the daily intake of vitamin B for such patients is maintained at the optimal level necessary for the normal functioning of the body, especially

increased intake of vitamin B. Practical experience, indeed, has shown that loss of appetite, constipation, fatigue, instability and other elements of the so-called neurasthenic syndrome are often readily removed by increasing the daily intake of vitamin B, and particularly of vitamin B<sub>1</sub>.

the nerves and gastro-intestinal tract, is the prescription of Bemax.

**BEMAX** supplies, at time of manufacture, approximately:

Vitamin A	280 i.u. per oz.	Vitamin E	8 mg. per oz.
Vitamin B <sub>1</sub>	240/420 i.u. ..	Magnesium	99 mg. ..
Vitamin B <sub>2</sub>	0.9 mg. ..	Phosphorus	330 mg. ..
P.P. factor	1.1 mg. ..	Iron	2.7 mg. ..
Vitamin B <sub>6</sub>	0.45 mg. ..	Copper	0.45 mg. ..

*Further particulars concerning Bemax from Vitamins Ltd. (Dept. B.E.), 23, Upper Mall, London, W.6.*

## STATRILIZED MORPHINE CARTRIDGES

- READY FOR INSTANT USE.
- IDEAL FOR EMERGENCY & A.R.P.
- SOLUTION PASSES DIRECT FROM CARTRIDGE TO PATIENT.
- EACH CARTRIDGE CONTAINS 1 c.c. STATRILIZED SOLUTION.

Statrilized Solutions of Morphine are self-sterilising and stable, with the added advantage of lessened toxicity. Statrilized Morphine may be used in exactly the same dosages as ordinary morphine solutions.

### CARTRIDGE SYRINGES & NEEDLES

**1 c.c. SYRINGE** (as illustrated) per 10/- syringe  
Needles for above, in boxes of 3, G.25, 1 in. long, stainless steel per 2 6d. box

**2 c.c. SYRINGE** to take cartridges of Novutox self-sterilising Local Anaesthetic and also 1 c.c. cartridges statrilized Drugs. per 20/- syringe

Needles for above, stainless steel, 1 in. or 1½ in. long, G.26, tubes of 12 needles per 4/- tube

Each c.c. of statrilized solution contains, in addition to the stated drugs, 0.00002 gm. capryl hydrocupreinotoxin hydrochloride.

### STATRILIZED DRUGS AT PRESENT AVAILABLE

STATRILIZED DRUGS	CARTRIDGES 20 x 1 c.c.	AMPOULES 12 x 1 c.c.	BOTTLES 12 c.c. 24 c.c.

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital statistics in the British Isles during the week ended Jan. 29.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for (a) England and Wales, London included, (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded as due to Infectious Diseases for (a) The 126 great towns in England and Wales, including London, (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases. A blank space denotes disease not notifiable or return available.

Disease	1944					1943 (Corresponding Week)

rate per 1,000 total births (including stillborn)			38					43		

Includes primary form or England and Wales, London (administrative county), and Northern Ireland.

Includes puerperal fever for England and Wales and Eire.

Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

## EPIDEMIOLOGICAL NOTES

## Discussion of Table

In England and Wales during the week the incidence of measles went up by 258, of diphtheria by 65, and of dysentery by 28 cases. There were 182 fewer notifications of scarlet fever, 111 of whooping-cough, and 43 of acute pneumonia.

The 104 deaths from influenza recorded in the large towns represent a decrease of 39. Deaths in Greater London fell from 54 to 39.

Measles appears to have begun its seasonal rise: notifications have increased from 515 to 919 during the past month and are now at the highest level for twenty-one weeks. The only rises of note during the week were in Lancashire by 68, London by 35, and in Durham by 28 cases. The rise in diphtheria was due mainly to Yorks West Riding 30 cases more, and Lancashire 27 more. Scarlet fever was less prevalent in the south-eastern and south midland regions: there were 43 fewer cases in Surrey. Whooping-cough notifications were down by 29 in Essex and by 28 in Lincoln. The only notable difference in the notifications of acute pneumonia was a decrease of 53 in London.

The one fresh outbreak of dysentery during the week was in Denbighshire, Colwyn M.B. 14. In Middlesex notifications rose from 11 to 27; in London they fell from 41 to 27. In the other established large outbreaks the incidence remained unchanged: Kent 20, Lancashire 20, Surrey 12, and Yorks West Riding 10.

In Scotland notifications of whooping-cough fell by 100, acute primary pneumonia by 24, measles by 22, and dysentery by 13; there were 31 more notifications of scarlet fever, due to the experience of the western area. Dysentery in Edinburgh increased from 7 to 19 cases, the only other large centre of infection being Fife county, with 11 cases.

In Eire diphtheria increased from 110 to 152 cases. The incidence was widespread, the largest returns being Dublin C.B. 33, and Co. Carlow, Carlow U.D. 27.

In Northern Ireland relatively large declines were recorded in the incidence of scarlet fever by 28, and of diphtheria by 20.

## Tuberculosis Figures

Mr. Willink furnished on Feb. 10 the following comparative figures for all forms of tuberculosis:

Year	Deaths from Tuberculosis		Notifications of Tuberculosis	
	England and Wales	Scotland	England and Wales	Scotland
1938	26,176	3,431	58,093	7,568
1939	25,623	3,526	53,835	7,097
1940	28,144	4,003	54,929	7,722
1941	28,670	4,174	59,976	8,294
1942	25,547	3,998	69,732	9,048

## Week Ending February 5

The returns of infectious diseases in England and Wales during the week included: scarlet fever 2,032, whooping-cough 2,116, diphtheria 733, measles 1,162, acute pneumonia 1,115, cerebrospinal fever 71, dysentery 161, paratyphoid 9, typhoid 5. Influenza deaths in the great towns numbered 78.

## Points from Abroad

According to Heismeyer (*Disch. med. W'schr.*, 1943, 69, 667) an attempt to rehabilitate the tuberculous alongside of the non-tuberculous was unsuccessful at Hohenlychen, even when the former were non-infectious. In spite of talks by doctors and others, the healthy workers had too great a fear of infection to tolerate the presence of the tuberculous in the workshops. Investigation of large numbers of people by means of x rays continues. Out of the cases of tuberculosis discovered in this way among 6 million people in Westphalia it was found that only 33.9% of those with active disease had previously been known to the health authorities as tuberculous.

Influenza has been prevalent in Denmark. In the second week in January there were 3,000 cases—mostly of a mild character—in Copenhagen.

Tins of sweetened condensed milk now contain 14 oz. and of unsweetened 16 oz., and the four-weekly allowances, free of points, for infant feeding have therefore been adjusted as follows: for children under 5 months up to 10 tins of the sweetened or up to 18 tins of the unsweetened milk; children 5 to 6 months inclusive 11 tins or 21 tins respectively; up to 9 months 12 or 23 tins, and 10 to 12 months 13 or 24 tins. It is assumed that 2½ tins of sweetened or 5 tins of unsweetened condensed milk will be available each 4 weeks on the infant's points ration.

## INCOME TAX

## Claims for Support of Mother and Brother

J. F.'s mother is a widow with a very small income and he sends most of his earnings to her for her support and for the education of his younger brother. What claim can he make?

\* He can claim an allowance of £50 if he "maintains" his mother, but that amount is reduced by £1 for every £ by which his mother's income exceeds £50.

## Enforced Removal

A. R.'s premises were bombed and he was compelled (a) to remove furniture to new premises, and (b) to buy new furniture, etc. Can he charge these expenses?

\* (a) Yes. (b) He can charge the cost of replacement in so far as it was not covered by insurance or other indemnities. (The answer of course applies to professional equipment.)

## Replacement of Cooker in Nursing Home

F. C. explains that in 1942 the kitchen range in her nursing home required replacement. A range similar to the old one was unobtainable, and an "Aga" cooker was installed. The inspector of taxes has restricted the allowance to F. C.'s share of the estimated cost of replacing the old range with a similar one.

\* The inspector is right in principle; the element of improvement represents capital outlay. On the other hand the estimate of £20 for the cost of replacing the old range with a similar one may be insufficient. We advise F. C. to press for a substantial increase and, if necessary, to obtain an estimate from a local builder on the point.

## Accommodation Provided on Crown Premises

C. G. is supplied with a bedroom and a sitting-room in a Ministry of Pensions hospital. The annual value of the rooms is estimated at £19 10s., and the inspector of taxes proposes to bring this amount into assessment under Schedule A as from April, 1941. Is this correct?

\* Yes—assuming that C. G. has had the use of the accommodation since April, 1941, and that the premises belong to the Crown. The liability arises because the exemption conferred on premises "belonging to the Crown" does not extend to "apartments . . . in the occupation of any officer of the Crown by right of his office or otherwise."

## Expense on Taking Over a Practice

"M.B., Ch.B." recently purchased a practice and inquires as to the allowance for (a) cost of removal from the town where he had been acting as a locum, (b) legal and other expenses in connexion with the purchase of the premises of the new practice, and (c) effecting some structural alterations to reduce domestic work and thereby free his wife for assistance in the practice.

\* (a) and (b). No deduction can be claimed for these expenses; they represent capital expenditure in order to carry on the practice. (c) This also falls under the ban as capital expenditure, but any reasonable amount paid to the wife for her assistance in the practice can be deducted.

## Service in the Forces: Professional Expenses

W. H. and J. N. M. inquire as to the allowance against Government pay for expenses incurred in the form of subscriptions to professional societies, and in replacing out-of-date medical books.

\* Official pay is assessable under Schedule E, and the rule with regard to expenses is that to be allowable they must be incurred wholly, exclusively, and necessarily in the performance of the duties of the office. If the employer—in the case of ordinary non-Government employment—requires his assistant to be a member of the B.M.A., for instance, then payment of the subscription is a "necessary" expense of that employment and the amount can be deducted. Such a requirement, however, does not apply to Government service, and neither is an officer required to maintain his medical books up to date, and consequently such expenses fall under the ban of the restrictions and rigid rule quoted above.

## "Pay as you Earn"

A. B. inquires whether the new system of deducting tax will apply to payments he makes to a married woman acting as locum for an absent partner. Her remuneration is £550 a year with car and all living expenses.

\* Yes. As from April 5 all individuals holding an office or employment will come within the new arrangements, whatever the amount of the remuneration.

## LETTERS, NOTES, ETC.

## Local Antiseptics

Mr. W. DOUGLAS PARK (London Hospital) writes: The use of sulphonamides, proflavine, and now penicillin has shown that local use of antiseptics is both justifiable and desirable. For years I have been using potassium permanganate solution as a local application on varicose ulcers. It is, of course, far from new as an antiseptic, but very few people seem to use it, and all have been impressed and usually rather surprised at its success when they do so. I use a 1 in 2,000 solution applied once or twice a day, even more often, and find that it produces a clean granulating wound in a remarkably short time in practically all cases. It has the notable characteristic of greatly diminishing the extremely unpleasant smell of these ulcers. I have found the solution useful on many other dirty wounds besides varicose ulcers, particularly chronic osteomyelitis following compound fractures. I write this short letter as I think it may prove helpful to others who may not have thought of using it.

## Treatment of Coryza

Dr. RUTH HUNTER (Sandwich) writes: Referring to Dr. Piney's letter (Jan. 29, p. 163) on the treatment of coryza with argyrol and argyrol in normal saline, and pointing out the instability of a solution containing these components, I should like to mention that a stable solution, isotonic with, or, to use a more homely term, "comfortable" to, the nasal mucous membrane and non-crust-forming, can be made by prescribing a 10% solution of argyrol in quarter normal saline. Ephedrine may be used if necessary five minutes before the argyrol to reduce congestion and so permit a more effective permeation of the argyrol in the nasal passages. The use of a spray is more effective and convenient than that of a dropper.

## Infusion of Fluid by Sternal Puncture

Dr. A. P. HARDMAN writes: I was most interested to read Mr. Hamilton Bailey's article (Feb. 5, p. 181) on the infusion of fluid by sternal puncture. In 1941 I saw the method very ably demonstrated by Dr. Mabel E. Carmer of New York State on an infant suffering from severe marasmus which was under my care. The extreme dehydration in this case had rendered intravenous infusion practically impossible. There is no doubt that this method of infusion can be of great value in such cases. I feel grateful to Mr. Hamilton for his clear review of what had appeared to me an unorthodox yet most rational method of administering fluids.

## War in the Nursery

The HON. SECRETARY of the National Society of Children's Nurseries writes: We see stated in your issue of Jan. 8 (p. 50) that in the war nurseries there is "a high incidence of infection and a low incidence of happiness." As a society we consider that this is a very grave allegation to make. It is a dangerous one to put forward at a time when the Government has found it necessary to make nursery provision for children of women whose work is essential to the effort to end the war. Such an allegation seems to us to be grossly exaggerated and needs to be substantiated. Surely it would have been more useful to influence those responsible to improve conditions in the nurseries which Dr. Helen Mackay has investigated. The power of your readers is immense if they wish to be assured that children are properly cared for in any nursery set-up. This society would welcome an expression of such determination from the doctors.

## Supplies of Iodine

The IODINE EDUCATIONAL BUREAU writes: May we point out an error of fact in the interesting article on "Skin Disinfection" in your issue of Feb. 5? Iodine is not, as stated, in short supply at present. The reserve stocks in this country are entirely adequate to meet all requirements for some years. In its memorandum "Economy in the Use of Drugs in Wartime," the Therapeutic Requirements Committee of the Medical Research Council placed iodine in the category of drugs essential for certain purposes but not for others and in the use of which economy should be observed. It added the essential qualifying note, however, that adequate supplies are available and that the need for economy relates to alcoholic solutions. We are aware of the importance of conserving supplies of alcohol at this time and have been working towards this end by advocating aqueous instead of alcoholic solutions of iodine—a policy endorsed by the Therapeutic Requirements Committee. Incidentally, the germicidal value of the aqueous iodine solution is superior to that of the so-called "tincture"—a fact demonstrated by Claudius so long ago as 1902 and confirmed many times since, notably by such masters in the field of disinfection as Bulloch (1929) and Colebrook (1941).

LONDON SATURDAY FEBRUARY 26 1944

## FAINTING IN BLOOD DONORS

REPORT TO THE MEDICAL RESEARCH COUNCIL PREPARED BY A SUBCOMMITTEE OF THE BLOOD TRANSFUSION RESEARCH COMMITTEE\*

The bleeding of donors that has taken place to meet war-time needs for blood and blood derivatives has aroused interest in the cause and nature of the faint that may occur during or after the donation of blood (Brown and McCormack, 1942; Greenbury, 1942; Poles and Boycott, 1942; Williams, 1942). If such faints could be prevented the work of the Transfusion Service would be facilitated, as, apart from the discomfort they cause the donor, they delay the bleeding procedure. Further, a faint may occur (Poles and Boycott, 1942) when the donor has returned to work, resulting in possible serious consequences where machinery is concerned. Two investigations were therefore instituted: (I) to identify factors that may be associated with fainting during blood donation, with a view to their correction, (II) to determine the frequency of delayed faints.

### I. FACTORS ASSOCIATED WITH FAINTING IN BLOOD DONORS

The inquiry into the possible factors associated with fainting was carried out between the months of May and August, 1942, in a number of bleeding centres in England and Scotland. Although the actual details of bleedings vary with the locality, the general procedure approximates to that previously described (Brown and McCormack, 1942). The fact that a card had to be filled in for the donor studied may have slightly slowed down the routine in some instances.

To measure the actual frequency of fainting in different classes of donors—e.g., men and women, the young and old, manual and clerical workers, etc.—it would be necessary to collect details of every person bled, whether fainting or not fainting (or at least of a large sample). The fainting rate—i.e., number fainting divided by number bled—could then be calculated for each class. The resulting figures would show whether there were any appreciable differences in incidence between the classes, and whether, therefore, it would be wise to reject certain types of donors as being too subject to fainting. This method of inquiry would, however, have placed a heavy strain on the centres by asking them to supply detailed information about large numbers of donors. It would have severely limited the number of questions that could be asked about the donor, so reducing the value of the inquiry.

As an alternative method of investigation the following scheme was adopted (see accompanying Record Card). The centres were asked to complete a card for (a) every donor who fainted during a bleeding procedure; (b) for the next donor bled by the same person. By this means the characteristics of those persons who fainted could be compared with the corresponding characteristics of an unselected group who did not faint. The data should show whether certain characteristics appear with a materially greater frequency in the fainting group

than in the non-fainting, and thus answer the main question at issue—viz., are certain features significantly associated with an increased incidence of fainting?

#### Definitions

A donor was regarded as having "fainted" if any of the symptoms or signs usually associated with fainting were shown (Brown and McCormack, 1942) and the severity necessitated a delay or alteration in the normal procedure. A list of such symptoms or signs was given (Question 20), ranging from the slight, such as a feeling of warmth, pallor, or dizziness, to the severe, such as vomiting, loss of consciousness, or convulsions. The expression "faint" or "fainting" in the tables and discussion that follow must always, therefore, be read in this sense. The great majority of faints comprised more than one of these signs or symptoms.

The bleeding procedure for which each record was required was the course of events from the donor's arrival at the centre until his or her departure. The incidence of fainting therefore deliberately omits those cases in which the faint took place after the donor's departure from the centre: these are the subject of the second investigation recorded here.

As already stated, the non-fainting donor who was to serve as a control to the one fainting was to be the next donor after

\* The thanks of the subcommittee are due to the Depot Directors and Regional Transfusion Officers of England and Scotland who collected the data which form the basis of this report and to Dr. Bradford Hill for carrying out the statistical analysis.

the faint who was bled by the same person. In the event of this control also fainting the next two cases were taken as controls. No departures from this rule were allowed. In fact, the centres did not invariably find it possible to provide the control case required. For example, the last donor bled by a particular bleeder on a given day may have fainted, so that no subsequent case was available. The discrepancy is not likely to affect the comparisons materially, since there were, in all, 335 control cases to 362 faints—not a serious departure from the required equality.

### Reliability of the Sample

Some check on the reliability of this sampling procedure is possible. It will be seen from the record card that certain times were asked—to show how long the donor had been at the centre before the faint occurred, etc. As it was, of course, impossible to foretell which donor would faint and which would not, it was necessary to keep a time sheet for every donor. This information was therefore available for the whole "population" of donors as well as for the samples of fainters and controls: the time sheets were returned by two of the largest centres. In the one (Centre S) the number of donors was 3,345, and cards were completed for 181 faints, giving a fainting rate of 5.4%. In the other (Centre M) the number of donors was 1,864, and cards were completed for 107 faints, giving a fainting rate of 5.7%. Applying these ratios to the various times recorded on the sample cards gives an estimate based upon the sample of the average time spent at the centre by the whole population. (For example, the average length of wait at the centre before bleeding was 14.2 minutes for the controls and 13.1 minutes for the fainters. As fainters were 5.4% of the total the average length of wait for the whole population can be estimated from the sample as  $(13.1 \times 5.4) + (14.2 \times 94.6) \div 100$ , or 14.1 minutes.) These values can be compared with those recorded on the time sheets for all the donors, and they give the results shown in Table I.

TABLE I

	Centre S		Centre M	
	From Time Sheets	Estimated from Sample	From Time Sheets	Estimated from Sample
Average length of wait (minutes) at centre before venepuncture	14.9	14.1	15.7	15.6
Average length of wait (minutes) at centre after venepuncture	24.1	25.9	32.6	32.3
Average length of time (minutes) between arrival and departure	43.9	47.9	52.9	53.4

The agreement is good, and shows that in this respect the samples give a correct picture of the "universe," and may therefore be accepted as likely to be satisfactory for the analysis of other features.

### Results

The results were analysed in four groups. Three groups—L, M, and S—each represented the donors bled at one particular centre, while the fourth (O) included the cards returned in small numbers from many different centres. Except when striking differences were observed between the different centres only the combined figures are recorded here.

1. *The Incidence of Fainting.*—The incidence was shown in a previous paragraph to be 5.4% of donors at S and 5.7% at M. For the other groups the information regarding the total number bled was not available. It may be noted that the incidence as defined in this inquiry must in part be affected by the length of time the donor is kept at the place of bleeding, since faints occurring after departure were classified as delayed and not included. The longer the donor is kept, the higher, therefore, may be the recorded rate, and vice versa.

2. *Sex and Civil State.*—Comparison of the sex and civil state of the control and fainting groups is shown in Table II. It will be seen from this that men are slightly under-represented in the fainting group, single women approximately equally represented in both groups, and married women slightly over-represented in the fainting group. The numbers involved are such that these differences between the controls and fainters are not more than might fairly easily be due to chance. However, this slight deficit of men and slight excess of married women in the fainting group was found on

detailed analysis to be a feature of each of the four separate bleeding centres. It is possible, therefore, that the difference, though certainly small, is real, and that, regarding single women as having an average fainting rate, men have a rate rather below and

TABLE II

	Number of Donors		Percentages	
	Controls	Faints	Controls	Faints
Men .. ..	98	88	29.3	24.3
Single women ..	101	105	30.1	29.0
Married women ..	136	169	40.6	46.7
Total .. ..	335	362	100.0	100.0

married women a rate rather above average. For one centre (M) it was possible to calculate the actual fainting rates for the sexes separately from the time sheets. They were found to be 3.9% in 361 men bled and 6.2% in 1,503 women, a difference of  $2.3 \pm 1.2$ . Again the difference is not technically significant, but suggests a lower rate of fainting amongst men.

3. *Age.*—The effects of age are shown in Table III.

TABLE III.—Percentages in Each Age Group

Age	Men		Single Women		Married Women		Total	
	Controls	Faints	Controls	Faints	Controls	Faints	Controls	Faints
Under 24 ..	15.5	20.5	46.0	45.7	11.9	8.9	23.2	22.4
25-39 ..	51.5	47.7	34.0	33.0	46.7	54.5	44.3	46.7
40 and over ..	32.9	31.8	20.0	20.9	41.5	36.7	32.5	30.9
Mean age	36.9	34.7	30.2	30.7	39.3	39.5	35.9	35.8

There is clearly no evidence in these returns that age is a factor of importance. The faints are spread over the whole span of ages represented, and the proportions at different ages are close to those shown by the control group. The mean ages of the two groups are nearly identical for men and women, single or married.

4. *Occupation.*—In studying the incidence of fainting in persons differently employed it was possible to divide the donors into three groups only—namely, those on clerical or similar work, those employed on factory jobs, and the remainder as a mixed group. At all ages combined the figures are shown in Table IV.

TABLE IV.—Percentages of Faints according to Occupation

Type of Work	Men		Single Women		Married Women	
	Controls	Faints	Controls	Faints	Controls	Faints
Clerical ..	32.7	31.8	34.7	48.6	10.3	6.5
Factory ..	31.6	34.1	27.8	23.8	12.5	14.8
Other ..	35.7	34.1	37.6	27.6	11.8	16.0
Housewives ..	—	—	—	—	65.5	62.7

There is no appreciable difference between the work of the controls and faints in men and married women, but we find an excess of clerical workers among the single women who faint which is just statistically significant ( $+ 13.9 \pm 6.8$ ). The results when subdivided by age give small numbers and record no consistent differences between the controls and faints except that, though apparent in all age groups, the high incidence in clerical workers among unmarried women is most apparent over the age of 35. In the question of relating to the donor's occupation it was also asked whether he or she sat or stood at work. In a number of cases there was, as would be expected, no simple answer, for certain jobs involve some sitting and some standing. The analysis was therefore directed towards enumerating those in the different groups who replied that they stood at their work. With men and married women there was no material difference between the control and fainting groups: 50% of the male controls and 48% of the faints stood at their work. With married women the corresponding percentages were 43 and 49. With single women a rather lower proportion of the fainters stood at their work—24%, against 36% of the controls, a difference which clearly follows from the higher incidence of fainting in the clerical workers in this group. Excluding these workers, few of whom stood at their work, a comparison was made of factory workers, shop assistants or managers, and all otherwise employed. The differences between the controls and the fainters are negligible in each group, the total for the three groups giving 50% of the controls and 57% of the fainters standing at their work. There is no evidence, therefore, that posture has any bearing upon the probability of fainting at blood donation.

5. *Length of Wait before Bleeding.*—It is possible that the length of time the donor waits before bleeding might affect the chances of fainting. Too long a wait might possibly be a disadvantage to the

nervous individual. On the other hand, under observations regarded as relevant it was occasionally stated that a donor who fainted had hurried to the centre, the inference presumably being that he or she arrived hot or tired, a condition which might have been corrected by a longer wait before bleeding. Table V shows, however, that the distribution of times of waiting and the mean time differs immaterially between the controls and the fainters.

TABLE V

Length of Wait before Bleeding (minutes)	Percentages	
	Controls	Faints
Under 10 .. ..	49.7	50.8
10-19 .. ..	26.6	27.2
20-29 .. ..	12.3	10.6
30-39 .. ..	5.4	6.7
40-49 .. ..	2.4	3.1
50-59 .. ..	3.6	1.7
Mean length of wait:		
Men .. ..	13.8	12.7
Single women ..	15.0	14.4
Married women ..	14.6	14.2
Total .. ..	14.5	13.9

On the average the fainters had been kept waiting a very slightly shorter time than the controls, but the difference is of the order of but half a minute. (It might, of course, be due to a slight delay occurring after a faint before the bleeding of the next donor.)

6. *Length of Time between Last Meal and Bleeding*.—There is no evidence from the data collected that a long interval since a meal may appreciably increase the incidence of fainting (Table VI).

TABLE VI

Length of Time since Last Ordinary Meal (hours)	Percentages	
	Controls	Faints
Under 1 .. ..	2.1	4.0
1 .. ..	22.2	22.0
2 .. ..	26.7	27.1
3 .. ..	18.5	17.5
4 .. ..	14.9	11.9
5 .. ..	7.1	7.1
6 .. ..	2.7	2.8
7 .. ..	3.1	3.1
8 .. ..	0.3	0.3
9 .. ..	—	0.3
10 or over ..	4.0	4.2
Mean interval:		
Men .. ..	3.1	3.3
Single women ..	3.6	3.7
Married women ..	3.6	3.4
Total .. ..	3.5	3.6

There is a small excess of long intervals in the fainting group—10.4% over 6 hours, compared with 8.2% of the controls—but more observations would be necessary to determine its significance. The average intervals for each sex differ inappreciably between fainters and non-fainters, being 3.5 hours for the controls and 3.6 hours for the fainters.

A further question related to the time at which any intervening snack was eaten, so that calculation should be made of the interval between bleeding and the last consumption of any food—i.e., back to the time of the snack or, if none had been eaten, to the last ordinary meal. Again the distributions of intervals and the average intervals are strikingly similar. For the total observations the average times were 2.4 hours for the controls and 2.5 hours for the fainters, and there is equally little difference in the subdivisions by men and women, married or single. But, as with the intervals since the last ordinary meal, there is a hint that too long a time may play a part in a small number of cases, for 1.8% of the controls and 3.3% of the fainters had had no food for at least six hours.

7. *Menstruation*.—In Table VII is shown the position of the date of bleeding in relation to the woman's position in the menstrual cycle. No appreciable differences between the controls and fainters are apparent. Of the former 18% and of the latter 19% were past the menopause, and are excluded together with a small number who gave no information or who were stated to be irregular in their interval. Only a relatively small proportion of women present themselves for bleeding during menstruation, and this proportion differs negligibly between the two groups. The majority come to be bled in the latter half of the cycle (menstruation due within 1-14 days), and only about half as many in the first half of the cycle (menstruation due in 15-28 days, or 1-14 days past the previous menstrual period). Here there is a difference of some magnitude between the controls and the fainters, for of the former 9.2% and of the latter

15.8% had recently completed a menstrual period. The difference is just statistically significant ( $6.6 \pm 3.3$ ), and suggests that the later part of the menstrual cycle is a more favourable time for bleeding than the earlier part.

TABLE VII

Menstruation*	Percentages	
	Controls	Faints
Present .. ..	8.2	9.1
Due now .. ..	4.3	3.8
In 1-7 days ..	29.0	25.4
" 8-14 .. ..	31.0	28.7
" 15-21 .. ..	17.4	17.2
" 22-28+ .. ..	9.2	15.8

\* Many intervals were recorded as exactly one week, two weeks, three weeks, † Including cases recorded as just finished.

8. *Difficulties Occurring in Bleeding*.—In the vast majority of cases—92% of the controls and 90% of the faints—free bleeding was achieved without difficulty. There was haematoma formation in 2.4% of the controls and in 1.9% of the faints; bleeding was unsuccessful in 0.6% and 0.8% and difficulties in securing a free flow occurred in 4.9% and 6.9% respectively. Though such difficulties may therefore have possibly contributed very occasionally to the occurrence of a faint they cannot be important in the general incidence.

9. *Number of Previous Bleedings and Associated Faints*.—There was in each group a slight excess of fainters whose blood donation was their first. The combined figures are shown in Table VIII.

TABLE VIII

No. of Previous Bleedings	Percentages		Ratio F/C
	Controls	Faints	
0 .. ..	47.9	54.1	1.13
1 .. ..	36.2	33.9	0.94
2 .. ..	11.0	8.4	0.76
3 or more ..	4.9	3.7	0.76

It is apparent that, while there is a slightly higher risk of fainting at a first donation, nearly half the fainters had been bled previously, some of them an appreciable number of times; previous uninterrupted donations are therefore no guarantee of similar success on a later occasion. On the other hand, it will be seen (Table IX) that a faint at the bleeding recorded was often associated with previous faints at blood donation.

TABLE IX.—Percentage of Previous Donations that were Associated with a Faint

	Controls	Faints
Men .. ..	1.3	29.7
Single women ..	8.4	42.9
Married women ..	2.1	35.1
Total .. ..	2.8	35.9

10. *History of Fainting not Associated with Blood Donation*.—Fainting not associated with blood donation was also reported far more frequently in those who had fainted at the bleeding under discussion than in the controls. Only 45 (13%) of the 325 controls gave a history of such fainting, against 159 (44%) of the 362 fainters—a difference of  $31\% \pm 3.2$ . It is of course possible that the occurrence of the faint at bleeding would lead the donor to remember or emphasize any previous history—more so than the donor whose bleeding was uneventful. While such a tendency would exaggerate the difference between the groups, it seems likely that much of that difference is real. The causes, for instance, to which previous fainting unconnected with bleeding was attributed show that the fainters referred much more often than the controls to a positive history in association with hospitals, minor surgical procedures, and slight accidents or injuries to the subject or others (9 of the controls to 47 of the fainters). Susceptibility to such influences would clearly be likely to tell against a successful bleeding.

11. *The Stage of Bleeding Procedure at which the Faint Took Place*.—Taking all the records together, a small proportion of the faints (2%) occurred at venepuncture or almost immediately; approximately a quarter (23%) started during bleeding; a third (34%) fell close to the time of withdrawal of the needle, with a further 16% following shortly afterwards; and the remaining quarter (25%) occurred during the final period of rest and recovery. The data were, however, not always easily interpreted. There are quite large recorded differences between Centre S and the other three centres. The former shows a much lower proportion of fainting in

the period of recovery and a much higher proportion at withdrawal of the needle. The figure in the final stages might well be related, as already pointed out, to the length of time the donor is retained at the centre; but, with the exception of L, this time did not vary appreciably. The average length of time the normal donor was kept resting-after bleeding was approximately 25 minutes at S and O, half an hour at M, and just over a quarter of an hour at L. No explanation in terms of these varying times seems possible, and there is nothing else in the available data to offer one.

12. *Symptoms shown by Fainters.*—The relative frequency with which various symptoms were noted in the fainting donors is shown in Table X (more than one symptom was usually recorded, so that the faint is entered under one or more headings).

TABLE X.—Percentage Frequency with which Various Symptoms were Observed. (Total No. of Faints, 362—Men 88, Women 274)

Symptom	Men	Women	Total
Feeling of warmth .. ..	73	62	65
Restlessness .. ..	17	14	15
Epigastric discomfort .. ..	25	25	25
Pallor .. ..	85	84	84
Dizziness .. ..	60	64	63
Blurring of vision .. ..	16	21	20
Sweating .. ..	80	50	57
Feeling of cold .. ..	14	14	14
Nausea .. ..	22	31	28
Vomiting .. ..	8	10	9
Loss of consciousness .. ..	16	12	13
Convulsions .. ..	7	8	7

Except for a higher incidence of warmth or sweating in males and somewhat more frequent complaints of nausea in women, there is little difference between the symptoms observed in the two sexes. Loss of colour took place in a great majority, other predominating symptoms being a feeling of warmth, dizziness, and sweating. Few symptoms were noted beyond those listed in Question 20 of the record card, there being a few each of sighing, diarrhoea, noises in the head or ears, and pains, tightness, or numbness in the chest, stomach, or limbs. Most cases had a number of symptoms, and it is not easy to classify them into definite type-groups. Broadly, it seems that about a quarter of the cases may be described as having slight symptoms—such as a feeling of warmth or sweating, dizziness, or a blurring of vision; another quarter had several slighter symptoms; while about 12% experienced epigastric discomfort, with and without other minor symptoms, 18% felt nauseated, and nearly 8% vomited. Thirteen per cent., or 1 in 8, lost consciousness.

13. *Length of Rest after Bleeding and Total Time at Centre.*—On the average, non-fainters rested some 25 minutes after bleeding (at one centre the figure was only 16 minutes), while fainters were kept another 20 minutes. The average total time the latter were at the centre was therefore approximately an hour and ten minutes, compared with three-quarters of an hour for the non-fainters. There was, of course, much variability round these averages from person to person.

14. *Observations Regarded as Relevant by those in Charge of Bleeding.*—The most frequent observations about fainting donors made by persons in charge of bleeding, apart from features already discussed, were that it was a hot day or that the room was stuffy, that the donor had been on night work or had had little sleep, was not well, was run down or worried by domestic affairs, had hurried to the centre, or had recently been working hard. Such observations were not, however, made in the case of non-fainting donors, so that there was no means of discovering whether such factors were indeed likely to be of importance.

## II. THE INCIDENCE OF DELAYED FAINTS

For reasons already stated a special inquiry was made into the true incidence of "delayed faints." With the co-operation of donors bled at the four London Blood Supply Depots such an inquiry was carried out in the spring of 1943. To avoid creating a feeling of alarm in donors it was considered inadvisable to draw attention to the possibility of the occurrence of a faint. Every donor bled over a specified period was therefore given a postcard on which was printed:

After the last bleeding  
on.....  
I felt specially fit  
I felt no difference  
I felt some discomfort, as follows:

The donor was asked to cross out what did not apply, and if any discomfort had been felt to describe it simply, giving the date and time when it appeared, and what the donor was doing at the moment. This card, signed by the donor, was returned in a business reply envelope the day after bleeding. The date of bleeding was filled in at the depot.

Eliminating a few cards which lacked sufficient information, there remained a total of 4,212 returns. In the case of three depots records were kept of the number of cards issued and the number returned: 3,442 were issued and only 272 were not returned. Comparison of the figures obtained reveals very little difference between the four depots. Just over three-quarters of the donors reported that they felt no difference: nearly another 10% thought themselves especially fit, giving a total of 86% unaffected or favourably affected by the procedure. The remaining 14%, or roughly 1 in 7, complained of some discomfort, though many complaints were of a trivial nature or of conditions not necessarily related to the bleeding. An example of the former is a slight feeling of lassitude for some hours after bleeding, and, of the latter, of a headache next day. The figures for the four depots agree in showing a slightly higher discomfort incidence in females than in males, the total figures being 11% of the men and nearly 16% of the women.

The complaints recorded are shown in Table XI, and it will be seen that in both sexes the feeling of tiredness is the most common one. It was reported by just over 5% of both men and women. These reports varied widely, from a "slight feeling of lassitude" to "felt very tired and washed out." Approximately 2% of both sexes referred to some pain or stiffness in the arm. Two per cent. of the men and nearly 5% of the women reported feelings of faintness or dizziness, but in many cases these were referred to as very slight or slight and transient.

The evidence, based as it is on individual reports, makes it difficult to determine with certainty the actual incidence of delayed fainting. The cases (4 men and 24 women) which are entered in Table XI under the heading "Fainted" include only those who reported loss of consciousness, or used such terms as "fainted," "collapsed," "black-out," etc. While these were undoubtedly the more severe cases they probably include a few donors who did not actually lose consciousness. Within this definition the incidence of delayed faints was 0.3% for men and 0.8% for women, each of the four centres showing very similar experiences. If inclusion be made of such reports as "almost fainted," "came over very faint," "had to lie down," etc., the incidence becomes 1.2% for men and 1.8% for women.

TABLE XI.—Type of Discomfort

Type Reported*	No. of Reports as % of No. of Persons Bled	
	Men (1,303)	Women (2,909)
Feelings of tiredness, lassitude, sleepiness, or the like .. ..	5.4	5.7
Stiffness or pain in the arm .. ..	2.1	1.9
Headache .. ..	0.5	1.4
Nausea, sickness, and biliousness .. ..	0.1	0.5
Giddiness, dizziness, or the like .. ..	0.5	1.8
Faintness or "felt faint" .. ..	1.1	2.2
"Fainted" .. ..	0.3	0.8
Other various complaints .. ..	0.9	1.3
Total .. ..	10.9	15.6

\* In some instances more than one type of discomfort was mentioned. Such cases have been allocated to what seemed to be the principal grounds of complaint.

## Discussion

It is not easy to compare the incidence of fainting found in a particular survey with that in another, as the definitions of a faint vary. For purposes of the present analysis a donor was regarded as having "fainted" if any of the signs and symptoms usually associated with fainting were severe enough to necessitate delay or alteration in the normal procedure. A similar definition was adopted by Greenbury (1942), and that of Williams (1942) approximates to it closely. Poles and Boycott (1942) applied the term only to a condition so severe that the donor lost consciousness or could obviously neither stand nor sit without doing so. It is therefore not surprising that the incidence of fainting was considerably lower in their series than in that of other workers. Their incidence was 2.8% in 10,000 donors. Williams records 6.85% in 4,317 donors; Greenbury 4.93% in 5,897 donors. In the present series it was not possible to make a complete study of incidence rates, but at two centres it was respectively 5.4 and 5.7%. It would

appear from these figures that under existing circumstances between 5 and 6% of donors may be expected to show some symptoms during or immediately after blood withdrawal.

Poles and Boycott consider that 1 in every 4 donors who faint loses consciousness; this high figure is obviously dependent in part upon their definition. In the present series only 13% lost consciousness. Figures are not given by Greenbury and Williams. The time in the bleeding procedure at which a faint occurs is variable, though the majority take place at the end of bleeding or shortly afterwards. In the present series 2% occurred at venepuncture, compared with 10% reported by Poles and Boycott. During bleeding 23% of faints are recorded here. Poles and Boycott record the occurrence of 6% before 400 c.cm. was withdrawn and of 5% in the latter part of bleeding. In the present series 34% occurred just before withdrawal of the needle and 16% shortly afterwards, while 25% happened during the rest period compared with 19% in this period mentioned by Poles and Boycott. The latter workers record 14% of delayed faints occurring after return to work, applying the term "faint" to anyone who either loses consciousness or can obviously neither stand nor sit without doing so. Within this definition only 1.8% of women and 1.2% of men in the present series fainted after they had left the depot. No explanation of this difference is available.

With the exception of Poles and Boycott, who describe a slight preponderance of male fainters, all observers agree that faints occur more commonly in women. This difference between the two sexes, while not in the present series statistically significant appears in all groups, and is probably real.

No effect of age on the incidence of fainting could be detected, though all previous observers have noted an increased tendency to fainting in younger donors. Williams suggests that this effect of age is more noticeable in men than in women. Greenbury (1942) has previously recorded a preponderance of clerical workers of both sexes in the fainting group. In our own series this preponderance of clerical workers was noted only in single women—the occupations of men and married women appeared unrelated to the fainting rate.

Medical officers in charge of centres are all of the opinion that donors who have been for several hours without food are more liable to faint than those who have recently had a meal. It has proved difficult to collect satisfactory evidence on this point, as in any series there are only a few individuals who have been many hours without eating. Williams points out a low fainting rate in donors who have had their meal within an hour of bleeding, and a definitely increased rate if the period is longer than five hours. In females bled within one hour of eating, the fainting rate was 3.72%, while in those who had not eaten for over five hours the rate was 10%. Poles and Boycott conclude that if the interval is 4½ hours or longer the number of faints is increased from 2.3 to 7.4%. The present investigation suggests that a lack of food could have played a part in only a very small proportion of cases, if at all.

Williams suggested that a high incidence of fainting was associated with menstruation—9.7% compared with 5.96%. We found no such association. Our figures suggested that fainting may be rather less frequent in the fortnight when menstruation is approaching than in the week after its cessation.

The one outstanding fact recorded in the present investigation that has not been previously noted is that 45% of donors who fainted gave a history of having done so on some previous occasion, either when giving blood or at the dentist, etc. This suggests that when the need for blood ceases to be so urgent prospective donors with a history of previous fainting for any reason should be discouraged.

#### Summary

An analysis in given of data collected from 697 blood donors, of whom 362 fainted during the bleeding procedure and 335 did not, he latter serving as a standard of comparison with the former.

The figures suggest that the incidence of fainting is rather lower in men than in single women, and rather lower in single than in married women.

There is no evidence that age, length of wait at the centre before bleeding, or difficulties in bleeding had any effect upon the incidence of fainting.

Menstruation was present at the time of bleeding in an equal number of fainters and non-fainters. Fainting was less common in the fortnight preceding menstruation than in the week after its cessation.

In general there is little difference between the fainters and non-fainters when divided into broad types of work (clerical, factory, and other jobs), but there is a suggestion that women clerical workers have a somewhat higher incidence.

A lack of food could have played a part in only a small proportion of the total number of faints.

A high proportion of fainters gave a history of fainting either at a previous donation or on some other occasion.

An analysis of symptoms revealed that 13% of donors lost consciousness, nearly 8% vomited, and 79% showed only mild symptoms.

Returns from 4,212 donors describing their feelings after bleeding showed that women complained rather more often than men. Of this total 10% reported that they felt especially fit, 76% that they felt no difference, and 14% that they experienced some discomfort, which was often slight. Only 1.2% of men and 1.8% of women recorded delayed faints, using this term in its widest sense. Under 1% of both sexes lost consciousness.

The data obtained are compared with those of previous workers.

It may be concluded (a) that, apart from excluding donors who give a history of fainting either associated or unassociated with blood donation, no factor that is open to correction has been found in connexion with fainting; (b) that, on analysis, the incidence of delayed faints proves to be extremely small.

## PULMONARY TUBERCULOSIS OF BOVINE ORIGIN

WITH NOTES ON BOVINE INFECTION IN THREE FAMILIES

BY

LESLIE J. CUTBILL, B.Sc., A.I.C.,

AND

ALAN LYNN, M.D.

(From Cheshire Joint Sanatorium, Market Droyton, Salop)

The results of investigations into the incidence of pulmonary tuberculosis due to the bovine type of tubercle bacillus in England and Scotland have been summarized by Griffith (1938). They show that pulmonary tuberculosis of bovine origin is more common in Scotland than in England.

Since 1934 the type of organism present in the sputum of 2,101 cases of pulmonary tuberculosis undergoing treatment in the Cheshire Joint Sanatorium has been determined. The results up to 1943 are as follows: human examined, 2,101; human, 2,052; dysgonic human, 1; bovine, 48; % bovine, 2.28. Most of these strains were isolated on a modified Loewenstein-Jensen medium (Edwards, Lynn, and Cutbill, 1936), though in a few instances guinea-pig inoculation was necessary. Strains which were typically eugonic on this medium were regarded as human. Dysgonic strains, and those differing in any way from typical eugonic strains, were subcultured on Loewenstein's medium and on glycerin-potato. Strains showing typical eugonic growth on subculture were accepted as human. Subcultures of all dysgonic strains, and of all strains not typically eugonic on subculture, together with specimens of sputum from the respective patients, if available, were sent to the late Dr. A. Stanley Griffith, at Cambridge, for confirmation of cultural characteristics and for virulence tests in rabbits. Latterly, rabbits were available here, so that not only the determination of cultural characteristics of strains but their virulence for rabbits have been investigated in parallel here and at Cambridge. The virulence for rabbits of the last 16 dysgonic bovine strains isolated since the illness and death of Dr. Griffith have been investigated at the Cheshire Joint Sanatorium by one of us (L. J. C.).

The presence of avirulent acid-fast bacilli in sputum has been reported by Griffith (1933). The expense involved precluded the use of virulence tests on all the eugonic strains isolated by us. However, guinea-pigs were inoculated with 100 eugonic strains, picked at random. All produced typical tuberculous lesions in these animals. In most of the 2,052 human-type cases, strains with the same cultural characteristics were subsequently isolated on one or more occasions. One of these strains was dysgonic human. In two bovine cases, treated by artificial pneumothorax, in which pleural effusions developed, typical bovine tubercle bacilli were isolated from the effusions as well as from the sputum.

The incidence of 2.28% of pulmonary tuberculosis due to bovine-type bacilli reported here is so far the highest recorded in England, though it is considerably less than the lowest Scottish figures. In Scotland the highest incidence (9%) bovine was found in a predominantly rural area. The area which the Cheshire Joint Sanatorium serves includes the administrative county of Cheshire, the cities of Stoke-on-Trent and Chester, and the county boroughs of Birkenhead, Wallasey, and Stockport. All cases of pulmonary tuberculosis in these areas do not come to this sanatorium, and no children under 15 years of age are admitted. The distribution of population and incidence of phthisis due to the bovine type of tubercle bacillus are given in Table I.

TABLE I

	Population	% of Total Population	No. of Bovine Infections	No. per 100,000 of Population
City and urban ..	1,247,000	89%	23	2
Rural ..	157,000	11%	25	16

Making due allowance for statistical error it is strikingly clear that in the part of England covered by this investigation, as in Scotland, it is the rural population which provides the greater proportion of bovine infections.

### Epidemiology

Griffith (1904-13, 1937), Cobbett (1917), Blacklock (1932), Lange (1932, 1937), Cumming and Foster (1933), Griffith and Smith (1935), Griffith and Munro (1935), and Munro (1939) have discussed in detail the various avenues by which the bovine tubercle bacillus can infect man. The standards set by the recognized authorities quoted above must be the measure of all epidemiological studies concerned with the spread of tuberculosis of bovine origin. The three principal avenues of infection by the bovine bacillus are:

1. *Alimentary*—ingestion of infected material, most commonly milk, either raw or insufficiently heat-treated.
2. *Air-borne droplet infection*—contact with cattle.
3. *Air-borne droplet infection*—human to human.

The factors which constitute the presumptive evidence of these three avenues are:

- (a) History of raw-milk drinking.
- (b) Evidence of alimentary tuberculous infection.
- (c) Cervical or other glandular involvement, bone or joint tuberculosis.
- (d) History of tuberculosis in early childhood.
- (e) Contact with cattle.
- (f) History of tuberculosis in the same family.

One or more of the factors enumerated above, with or without bacteriological confirmation, may be present, but it is often difficult to obtain clear decisive evidence of any one source of infection: proof is most likely to come from the accumulation of presumptive evidence.

### Milk

Some of the primary infections in our cases must have occurred several years before this investigation began in 1934. The time which has elapsed makes it impossible to get reliable information regarding the condition, quality, or quantity of milk supplied in the area covered. The possibility of infection by bovine bacilli in milk definitely existed. The annual reports of the medical officers of health in the years 1934 to 1939 show that milk examined for *M. tuberculosis* did contain virulent

bacilli in from 2% to 17% of the samples taken, the figures fluctuating widely from year to year.

Habitual milk-drinkers we define as drinkers of raw milk regularly as an article of food. We have no really satisfactory history of the milk-drinking habits of the human cases in our series, but we have more complete details of our bovine cases. The most we can say is that we have no evidence of any excessive milk-drinking in this area similar to that found by Griffith and Smith (1935) in North-East Scotland.

Cooked milk, such as in puddings, has been excluded as a source of infection because the time and temperatures required to bake and cook are far above those lethal for *M. tuberculosis*. We presume that most of the individuals in our series took milk in tea or other beverages; but would point out that milk so taken is exposed to conditions similar to "high-temperature short-time" sterilization. We have no evidence as to what would happen to infected milk if exposed to such conditions. This point is being investigated. One case (H.J.) in our familial-infection group was definite about not drinking milk, and only took condensed milk in his tea.

TABLE II.—48 Bovine Cases: Probable Mode of Infection

Alimentary	Air-borne Cattle Contact	Air-borne Familial	No Evidence Obtained	Total
16 (33%)	10 (21%)	3 (6%)	19 (40%)	48

The sixteen alimentary cases include 7 habitual milk-drinkers. 5 with cervical gland infection only, 2 habitual milk-drinkers with cervical gland involvement, 1 habitual milk-drinker with tuberculosis of the spine, and 1 case of tuberculosis of the hip. The 3 air-borne familial cases include one who had contact with cattle and took a "little milk."

Histories of milk-drinking and indications of an alimentary source of infection we have regarded as strong presumptive evidence of milk as the most probable cause. (See Table II: 16 cases (33% of total bovines).)

Included in the milk, gland, and bone infections are cattle contacts (see Table III); these have been withdrawn from the cattle-contact group because of histories of milk-drinking or glandular or bone tuberculosis. On the evidence available the source of their infection was most probably milk. No case has been included under more than one head. In the 19 cases in which no evidence was forthcoming of any source of infection cattle contact can be ruled out; also there was no evidence of familial infection. Milk-borne infection cannot be excluded; these patients were definite that they were not habitual milk-drinkers.

### Cattle Contact

The incidence of bovine cases in cattle-contact and non-cattle-contact groups is as follows: 97 cattle contacts, 16.4% bovine; 2,004 non-cattle contacts, 1.6% bovine. The occupation of our cattle contacts and the type of organism isolated are given in Table III.

TABLE III

Occupation	Human	Bovines		Total
		Cattle Contact only	Milk-drinkers with Glands	
Farmer ..	7	6	4	17
Farm labourer ..	44	3	1	48
Tanner ..	2	1	0	3
Butcher ..	17	0	1	18
Dairy worker ..	9	0	0	9
Lairage labourer ..	1	0	0	1
Women's Land Army	1	0	0	1
Total ..	81	10	6	97

Farm labourers included several general labourers who had at some time worked on a farm for a period of not less than one month. In these cases there was probably very little and no prolonged contact with cattle.

The removal of all cases with alternative sources of infection from the 16 bovine cattle contacts leaves us with 10—6 farmers, 3 farm labourers, and 1 tanner, who were definite about no

drinking raw milk and who showed no clinical evidence suggestive of milk-borne infection or familial tuberculosis.

It is an established fact that cattle can and do acquire primary pulmonary lesions and that it is easy to infect animals by inhalation but difficult to infect by feeding them with tuberculous material (Royal Commission Reports, Cobbett 1917). Cattle can be infected by droplet; Munro (1935) recorded an instance in which an attempt to produce a herd of cattle was frustrated by the herdsman, who was found to be suffering from open phthisis and coughing up bovine bacilli, thus continually infecting fresh cattle. Blacklock (1932) showed that primary lesions do occur in the thorax. He felt justified in assuming that subjects with the primary lesion in the thorax were not infected by way of the alimentary tract but direct through the air passage. We cannot say with absolute certainty that in our 10 cases the lung lesion was primary, but the absence of any evidence of alimentary infection or tuberculosis in early childhood, and the history pointing to infection in adult life, suggest strongly that an occupation which involves contact with cattle also involves the risk of contracting bovine tuberculosis. This is particularly noticeable among farmers whose contact with cattle is likely to be more prolonged and more constant than that of other cattle contacts (Cumming 1933). This risk is probably not entirely removed by the slaughter of the cattle, as a tanner was found to have bovine tubercle bacilli in his sputum.

#### Human to Human

The possibility of human-to-human infection with bovine bacilli was investigated. Griffith and Munro (1935), Griffith and Smith (1935), and Cumming and Foster (1935) admit the possibility of human-to-human transmission. Evidence of more than one person in a family suffering from tuberculosis is common; bacteriological evidence is often difficult to obtain. Griffith and Munro (1935) were of the opinion that in one family investigated there was probably a common source of infection in milk; whereas in the other family the facts were more complex. In the latter both husband and wife had a family history of tuberculosis and a personal history suggesting infection before marriage. The presence in both individuals of bovine strains of attenuated virulence strongly suggested marital infection.

In the present series the family histories of the 48 bovine cases were as follows: positive, 9; negative, 39. The results of examining the 9 positive family contacts were: dead, 2; sputum specimens unobtainable, 4; bovine bacilli isolated, 3; human bacilli isolated, 0. Of these 9 bovine cases with a positive family history of tuberculosis 3 had relatives whose sputum contained bovine-type tubercle bacilli. Two of these relatives were admitted to this sanatorium suffering from pulmonary tuberculosis, and are included in the 48 cases of bovine phthisis. The third is not included, as the sputum specimen from this case was specially obtained because of the family history. There are therefore three families in each of which two individuals are suffering from pulmonary tuberculosis due to the bovine type of bacillus, as follows: family A, father and son; family B, father and daughter; family C, husband and wife.

TABLE IV.—Details of Three Families with Bovine Phthisis

Family	Members with Bovine P.Tb.	Age	Occupation	Milk-drinker	Type of Pulm. Lesion
A	Father (D. H.)	41	Farm lab.	No	Chr. fib. caseous
	Son (G. H.)	24	" "	Little	Subacute "
B	Father (S. J.)	44	" "	Yes	Chr. fib. Subacute "
	Daughter (A. J.)	18	Domestic	No	" "
C	Wife (M. J.)	39	Housewife	"	Chr. fib. "
	Husband (H. J.)	40	Clothier	"	" "

In each family the first-mentioned member was probably the first to be infected.

A striking feature of these cases is that in each family the member whose infection was probably the earlier was a cattle contact, and in only one instance a milk-drinker. None of these showed any clinical evidence of infection by ingestion. This suggests that the primary source of infection was contact with tuberculous cattle. In this connexion family C is of

further interest. The wife (M. J.), the daughter of a farmer, had three sisters, of whom two had no direct contact with cattle and did not develop tuberculosis. M. J. and the other sister worked with cattle, and both developed pulmonary tuberculosis, of which the sister died before this investigation began. The type

of organism therefore being unknown. The husband (H. J.) was fit and well, had no tuberculous family history before marriage or contact with cattle at any time, nor did he drink milk. From both husband and wife fully virulent bovine strains were isolated. H. J.'s infection was probably due to contact with his wife.

Similarly, in family B the only known source of infection was the father. The second infection in this family was probably due to human-to-human transmission. In family A the second member infected was in contact with his tuberculous father, but he was also in contact with cattle, and drank a little raw milk. The father was the probable source of infection, but contact with tuberculous cattle and milk-borne infection cannot be excluded.

#### Summary

The number of cases of pulmonary tuberculosis due to bovine-type bacilli among 2,101 cases in a sanatorium was 48 (2.28%), the highest so far recorded in England.

Infection from milk most probably occurred in 16 cases (33%).

In 19 cases (40%) no direct evidence of any source of infection was found, though milk-borne infection could not be excluded.

Evidence of infection by direct contact with cattle is strongly suggested in 10 cases (21%).

Details are given of three families, in each of which two members were found to have pulmonary tuberculosis of bovine origin. The original source of infection in each family was probably contact with tuberculous cattle, and the subsequent infection of the other member was probably due to human transmission of bacilli of bovine type.

In addition to the danger from infected raw or inefficiently pasteurized milk, the occurrence of human-to-human, cattle-to-human, and human-to-cattle infection becomes increasingly difficult to ignore.

Bovine-type bacilli were recovered from pleural effusions following artificial pneumothorax in two cases of bovine phthisis.

We record our grateful thanks to the late Dr. A. Stanley Griffith of Cambridge for his generous help and advice, and to Dr. Peter W. Edwards, medical superintendent of the Cheshire Joint Sanatorium, for invaluable help and criticism throughout this investigation and for permission to publish these results.

## PATCH-TESTING IN AN EAST COAST TOWN

BY

ELENORA J. SIMPSON, M.B., Ch.B.

(Children's Department, James Mackenzie Institute for Clinical Research, St. Andrews)

For the last 20 years the majority of St. Andrews children have had a routine medical examination from birth. From 1920 to 1940 88% of all children born to permanent residents in the town were seen at the child welfare centre, while 55% of these attended the James Mackenzie Institute after they reached 2 years of age. In addition, some of those born outside the burgh and temporary residents in St. Andrews attend the clinics. The children are examined at the Institute three times a year until they reach school age, and thereafter once a year until they begin work. Information obtained from the family doctor, the school medical officer, and specialist services (ophthalmic, orthopaedic, tuberculosis) is added to the records. It is noteworthy that all classes of the community attend. Thus a proportion of the child life in St. Andrews, a seaside and holiday resort, is available for research.

## Method

It was thought that it would be of value to discover what number of these children reacted to the Vollmer patch test (V.P.T.) for tuberculosis, and to try to relate the findings to clinical history and examination. Therefore, in 1941 the V.P.T. was added to the routine examination of all the children of whom we had a recorded history since birth.

The test consists in the application to the skin over the sternum, or on the back between the scapulae, of a strip of adhesive tape on which are three squares of gauze, the two outer squares having been saturated with old tuberculin and dried, while the central one is a control of dried glycerin broth. The skin must be thoroughly cleaned with acetone and allowed to dry before the patch is applied. The patch is left on for 48 hours, during which time it must not be allowed to get wet. Results are read 24 or 48 hours after removal of the patch. A positive finding is one in which the skin beneath the two outer squares shows a definite square of erythema. In strongly positive cases some vesiculation and a spreading of erythema occur, accompanied by itching.

In this investigation the result was read 24 hours after the removal of the patch, the child being visited at home for this purpose. Positive results were noted as one, two, or three pluses, according to the degree of the reaction—a pink square being +, a deeper red with slight raising of the skin ++, and a definite vesiculation and an erythema spreading from the site of the original square +++. The proportion of the degrees of reaction was 46% +, 26% ++, and 28% +++. Some attempt was made to assess the importance of the degree of reaction.

With regard to the reliability of this test for tuberculosis, Vollmer (1940) reports that ten different investigators made comparative studies of 4,285 cases and found 1,114 positive reactions to the patch test, as compared with 1,119 positive reactions to the Mantoux test; but other workers have not confirmed this degree of accuracy. The majority of reports indicate that the patch test is accurate in 95 to 98% of young patients (B.M.J., 1942, 2, 101).

## Results

Five hundred patches were obtained direct from New York through the courtesy of Messrs. Lederle, and results from 487 children aged from 2 to 16 years were obtained. Four children were examined twice, and nine patches were spoilt through being removed too soon. Refusal to allow the test was met with in only three instances.

There were 340 (69%) negative and 151 (31%) positive results in the 491 examinations. Of the four re-examined children who were originally negative three had become positive and one remained negative. Table I shows the numbers and results at different ages. In all positive cases an attempt was made to find the source of infection, and the work was linked up with that of the family doctor and the tuberculosis officer. St. Andrews is well supplied with T.T. milk, but a large proportion of the population use non-T.T. or unpasteurized milk.

TABLE I.—Showing Age at Examination of St. Andrews Children and Results of the V.P.T.

Year of Age:	2	3	4	5	6	7	8	9	10	11	12	13	14	14+	Total
V.P.T. neg.	16	68	38	32	35	22	23	25	17	15	17	13	5	14	340
" pos.	1	12	12	16	7	9	12	13	17	10	11	6	9	16	151
Total ..	17	80	50	48	42	31	35	38	34	25	28	19	14	30	491

Out of 500 possible tests, 9 were spoilt and 491 completed on 487 cases.

If these children are grouped in ages it will be seen that the percentage of positive results rises with age:

(a) Up to and including 5 years (195 children)	.....	21% positive
(b) 6-10 years	(180 " )	32% "
(c) Over 10 years	(116 " )	45% "

These percentages of positive reactors are slightly higher than those recorded by Crowe (1942) in percutaneous and Mantoux tests carried out mostly on dispensary patients who were considered free from active tuberculosis. Gilchrist *et al.* (1942) found 36% of positive reactions to a patch test in 385 adolescent boys who volunteered for the Air Training Corps. Shaw (Price, 1942), Belfast Tuberculosis Dispensary, using P.P.D. in two strengths, examined 1,634 contacts and non-contacts, aged from 1 to 14 years, and had 34% positive reactors.

The histories of the four children who were re-examined with the V.P.T. are as follows:

Case 1.—This boy, aged 4, negative Jan., 1942, was subsequently in close contact with a grandfather who died of pulmonary tuberculosis; in June, 1942, the child developed pleurisy, and was positive (+++) to the V.P.T. He has done well with sanatorium treatment.

Case 2.—This child, aged 5, was negative in Oct., 1942. He was x-rayed because his younger sister and older half-brother were positive reactors, and he had moist rales and a few rhonchi. The x-ray report was: "Definite enlargement of hilar glands with shadows spreading from root into right upper lobe, very suggestive of early infiltration of the lung." The child then developed measles and bronchopneumonia. In March, 1943, the V.P.T. was positive (++) and the x-ray report was: "The enlargement of the glands at the lung root is less marked, but there is now a definite lesion of the right upper lobe. The lower interlobar septum is well defined, and the appearances suggest there has been a small interlobar effusion." He had gained 4½ lb. in weight, had "never lost his appetite" in the five months, and looked well.

Case 3.—Aged 6, this boy was negative in June, 1941. His nutrition was only fair, and he had had a febrile attack three months previously. In March, 1942, the health visitor found him with a temperature and referred him to his family doctor. He was off school for a month, and was not seen again at the Mackenzie Institute until June, 1942, when clinically he had tuberculosis of the left lung and the x-ray report was: "Some enlargement of root glands with commencing calcification. There is a small area of infiltration in the left upper lobe." The V.P.T. was positive (+++). He has done very well with sanatorium treatment.

Case 4.—This patient had a history of infantile eczema and asthma. He was negative in July, 1941, and a few months later developed cervical adenitis, which required operation. The surgeon considered the glands tuberculous, but the V.P.T. was negative in April, 1943.

## Radiography

An x-ray examination of the chest was made in 131 of the 151 positive reactors; the remaining 20 were working and unable to attend, had left the town, or their parents refused to allow x-ray examination. Dr. B. W. Anderson, deputy county medical officer for Fife and acting tuberculosis officer for East Fife, has kindly examined the films and classified them in Table II.

TABLE II.—Results of X-ray Examinations in 131 Children with Positive Reactions to the V.P.T.

Cases	Tuberculous Lesion of Lungs or Pleura	Require Further Observation	Calcified Primary Focus	Enlarged Hilar Glands	Calcified Nodes	Normal Limits
131	5 (3.8%)	14 (10.7%)	1 (0.8%)	8 (6.1%)	41 (31.3%)	62 (47.3%)

Sixteen negative reactors were also x-rayed, and the films were classified. One showed calcified nodes, two had enlarged hilar glands, and the remaining thirteen were within normal limits. It was realized that sixteen was a totally insufficient number for a control group. The ideal would have been to

ray the whole 487 children. Of the five children showing definite tuberculous lesions, one, aged 3 years, came for routine examination; her mother said she had "seemed tired the last few weeks." The V.P.T. was strongly positive, and x-rays revealed military tuberculosis. She died three weeks later. Another, aged 7, had close contact with his tuberculous father, who died in 1941. The remaining three are Cases 1, 2, and 3, mentioned above.

### Housing

The housing of the children is shown in Table III under categories A (good), B (fair), and C (poor). The classification of the houses was made by the public health authorities. In the quinquennium 1921-5 only 41% of St. Andrews children were born in "good" houses; but 628 new houses have been built since that time and a number of old houses reconstructed. It will be noted that, out of the total of 487 children examined, 156 (94%) were well housed at the time of this investigation, and that therefore only 31 (6%) children living in B or C houses were examined with the V.P.T.

TABLE III—Housing

	A	B	C	Total
Negative reactions	111	20	3	134
Positive ..	143	7	1	151
Total	456	27	4	487

Combining B and C, a fourfold table gives:  $\chi^2 = 0.199$ ;  $P = 0.66$ . There is therefore no significant difference between the housing of the two groups.

### Morbidity

The mass of data available in each child's record, which is complete from birth, made it difficult to select points in the case history suggestive of tuberculosis. Also, the range of age of the 487 children—from 2 to 16 years—renders any analysis of little value statistically. However, it may be of interest to record that the case histories were examined under the following readings: (i) contact with notified or suspected pulmonary tuberculosis; (ii) respiratory disorders of a degree of at least two attacks of bronchitis or one of pneumonia; (iii) febrile attacks; (iv) operation on cervical glands; (v) poor nutrition; (vi) allergy; (vii) negative to i-vi. The findings are given in Table IV.

TABLE IV.—Showing Morbidity in 487 Children examined with the V.P.T.

No. of Cases	i Contact	ii Respiratory	iii Febrile-cula	iv Gland Operations	v Poor Nutrition	vi Allergy	vii Record Neg. for i-vi
V.P.T. neg., 336 (15%)	50 (15%)	32 (6.8%)	10 (3%)	5 (1.5%)	22 (6.5%)	11 (3%)	233 (69%)
V.P.T. pos., 151	32 (21%)	13 (12.5%)	12 (8%)	5 (3%)	11 (7%)	13 (9%)	81 (54%)

As would be expected, the morbidity is higher in the positive reactors, but it should be noted that 81 (54%) had none of the above signs or symptoms suggestive of tuberculosis. The consensus of opinion is that one cannot differentiate human and bovine infection by tuberculin tests. The fact that five negative reactors had had cervical gland operations strengthens the impression that the V.P.T. does not react so well to bovine infection. Also, one of the children examined was proved bacteriologically to have a bovine infection of lung and kidney, and she was a negative reactor.

### Summary

The investigation was undertaken as a specific piece of research on the lines of the original aims of the James Mackenzie Institute "to investigate disease before the occurrence of any structural change in any organ of the body, with a view to providing a diagnosis at a period earlier than is possible by the methods now in use, and in order to obtain a knowledge of the circumstances that favour the onset of disease."

Four hundred and eighty-seven children in a seaside and holiday resort were examined with the Vollmer patch test for tuberculosis, and 31% gave a positive reaction. The children were unselected except for the fact that all had health records from birth. Their housing conditions are tabulated. An analysis is given of the x-ray

films of chests in 86% of positive reactors. An attempt has been made to compare morbidity of positive and negative reactors.

Acknowledgment is due to Dr. James Orr, Director of the James Mackenzie Institute, for permission to publish this paper; and thanks are expressed to Dr. B. W. Anderson for his indispensable help with the x-ray films and for valuable encouragement and suggestions.

## SULPHAGUANIDINE IN THE TREATMENT OF FLEXNER DYSENTERY

BY

H. G. SMITH, B.Sc., Ph.D., M.B., Ch.B.  
 (Knightswood Fever Hospital, Glasgow)

The treatment of dysentery with sulphaguanidine has not gained the measure of approval accredited to the use of the other sulphonamides in many other infections. At least at this hospital the results were not entirely conclusive, although it is true that the majority of cases were of the Sonne type, against which sulphaguanidine is said to be less effective. It should be appreciated that any antibacterial agent is set a severe task when endeavouring to "sterilize" the bowel. The total length of the gut, its further increase in surface area by the throwing up of mucous membrane into folds, together with the dilution of the drug in faecal contents of the bowel, present a major problem in an attack on all parts of the intestine. It was thought that success might follow the administration of relatively large doses of sulphaguanidine, which, by reason of the poor absorption of the drug, would result in a high concentration of the presumed bacteriostatic agent throughout the bowel.

### The Investigation

The admission of 44 young female adults, ranging in age from 17 to 37 years (average 21), suffering from Flexner dysentery has given an opportunity of testing the effects of large doses. Unfortunately, when the early admissions were made it was not suspected that such a large number of patients would arrive ultimately, otherwise a controlled observation would have been planned. Certain points, however, make the results worth recording. Of the patients only ten had a record of diarrhoea before admission. The remainder were symptomless contact carriers. Five had received sulphaguanidine before admission, but not more than 10.5 g. During the period in hospital the only clinical manifestations reported were transient blood and mucus in the stools in four and mucous stools in two cases.

**Dosage.**—The total amount of sulphaguanidine was 142 g., given orally, over 10 days as follows: 24, 24, 24, 18, 18, 9, 9, 6, 6, and 4 g. A number of patients developed a toxic rash (described below), whereupon the drug was stopped; but in no

Graph showing sulphaguanidine blood levels.

case did any patient receive less than 129 g. in all. The level of sulphaguanidine in the blood was estimated for each day by random selection. Only one specimen of blood was withdrawn from most of the patients, but in some a second estimation

was made. The first three specimens, taken during the second or third day, were surprisingly high, ranging from 10 to over 14 mg. per 100 c.cm. Accordingly the fluid intake was increased from 4 pints to 6 pints a day. The average blood concentration for each day is represented graphically (see Fig.). It will be seen that the blood concentration follows a pattern essentially similar to that of the daily dose of the drug.

**Bacteriological Results.**—The bacteriological results obtained at the end of treatment were very satisfactory. Over a period of 14 days three successive rectal swabs and two specimens of faeces from each patient were examined: The stools were non-dysenteric in character, and both faeces and rectal swabs were found to be negative for *B. dysenteriae* (Flexner). In addition, magnesium sulphate was administered to 6 patients to produce watery stools: these gave negative results for *B. dysenteriae* (Flexner).

**Toxic Effects.**—Previous experience had shown that children tolerate massive doses of sulphaguanidine with no adverse effects. As much as 168 g. of the drug has been given over 16 days, and 330 g. over 28 days, to children aged 2 years. It was surprising, therefore, to find that no fewer than 21 of the 44 adult patients developed a toxic rash between the eighth and tenth days of treatment—mostly on the ninth day. With one exception all the rashes were pink and maculo-papular. Ten were generalized morbilliform rashes (one of which was petechial before fading). In one instance the rash was at first scarlatiniform, but later the same day it became morbilliform in type. The remainder were localized to particular parts of the body, such as the thighs, back, arms, or face. In one case a circinate urticarial rash was recorded. Here, small red macules appeared on the outer aspects of the thighs, spreading out with a pink raised edge to a diameter of about 2 in. and fading in about 24 hours. Three crops occurred before the rash disappeared entirely after 4 days. In other cases the rash faded in from 2 to 3 days. There was little constitutional upset, though a few patients complained of a burning sensation of the face. Two had more severe symptoms, with elevation of temperature to 100° and 101° F. generalized rash, a burning sensation of the skin, swollen face, and pink and suffused eyes.

Longcope (1943) suggests that the following sulphonamide rashes occur in chronological order: (1) urticarial, (2) scarlatiniform, (3) morbilliform, (4) petechial. Hageman and Blake (1937) described ten cases of toxic rash from their series of 134 cases occurring about the seventh and eighth days, and often found a leucocytosis with increase in percentage of eosinophils concomitant with the rash. There was no evidence of a leucocytosis in the present series, though in the majority of cases an increase in the percentage of eosinophils was noted. There was no correlation between concentration of the drug in the blood and the development of a rash. The early blood levels were not higher than the rest of the cases, and at the time the rash appeared the blood levels were usually negligible. No case which developed a rash had received previous treatment with sulphaguanidine.

**Sensitization.**—In view of the occurrence of such a high percentage of toxic rashes it was decided to obtain information regarding hypersensitivity to the drugs of the sulphonamide series. Accordingly 12 of the 21 cases were divided into 4 groups of 3 individuals, who were given the following single test dose: Group 1, 1 g. sulphathiazole; Group 2, 1 g. sulphathiazole; Group 3, 1 g. sulphadiazine; Group 4, 2 g. sulphaguanidine. No reaction was obtained with the first three drugs. With sulphaguanidine only one patient of the three showed a reaction. A scarlatiniform rash on face and chest made its first appearance one hour after administration, and five hours later became generalized and blotchy. There was no constitutional upset, and in 20 hours the rash had faded. The 9 patients who had previously received the other sulphonamides were later given 2 g. of sulphaguanidine. Seven developed a toxic reaction as follows:

1. Scarlatiniform rash developed on face, neck, and elbows 6 hours after administration. Eyes suffused and painful. Slight elevation of temperature. Faded 12 hours after appearance.
2. Scarlatiniform rash on arms and thighs appeared within 7 hours. Rash faded 12 hours later.
3. Generalized scarlatiniform rash appeared in 7 hours, with suffusion of eyes, photophobia, and sickness. Faded 12 hours later.

4. Generalized scarlatiniform rash appeared in 6 hours. Eyes suffused. No discomfort. Disappeared 11 hours later.

5. Generalized scarlatiniform rash appeared in 6 hours, with severe constitutional symptoms—viz., headache, sickness and vomiting, suffusion of eyes; and elevation of temperature.

6. Generalized scarlatiniform rash appeared in 7 hours. Faded 12 hours after appearance.

7. Scarlatiniform rash on legs appeared in 7 hours. Faded 11 hours after appearance.

### Discussion

From the therapeutic point of view the results were very satisfactory. It is unusual to obtain five consecutive negatives from a series of cases of dysenteric infection. On the debit side, however, the occurrence of so many toxic rashes must be regarded seriously, and constitutes a strong argument against massive dosage. It may be suggested that the total dose should not exceed 110 g. in the adult. The results of the investigation of the drug sensitization are considered interesting, and the conclusion drawn is that the primary hypersensitivity encountered was not general for sulphonamides but was confined to sulphaguanidine alone. The evidence seems to suggest that the hypersensitivity was due to the guanidine radical of the sulphonamide compound.

### Summary

Forty-four young female adults, mainly symptomless carriers of *B. dysenteriae* (Flexner), were treated with massive doses of sulphaguanidine.

The bacteriological results were satisfactory after conclusion of treatment. Five consecutive negative results were obtained for each patient.

About the ninth day of treatment 21 patients developed a toxic rash. Apart from one circinate urticaria, the rashes were pink and morbilliform. The presence of a scarlatiniform and a petechial type was noted among the latter. There was no relation to a high blood concentration of the drug.

Eight patients out of 12 reacted to a sensitization dose of sulphaguanidine. In some cases the constitutional upset was severe. There was no response to sensitization doses of other sulphonamides. It is suggested that the guanidine radical may be the sensitizing agent.

The high incidence of toxic rashes suggests care in dosage.

I wish to thank Dr. T. Anderson, superintendent of Knightswood Hospital, for constant advice and encouragement throughout this investigation. Thanks are also due to Dr. W. R. Wiseman, Glasgow Public Health Laboratory, who performed the routine bacteriological examinations.

## HAEMOLYTIC DISEASE OF THE NEWBORN THE PREPONDERANCE OF HOMOZYGOUS Rh-POSITIVE FATHERS

BY

G. L. TAYLOR,\* M.D., Ph.D., M.R.C.P.

AND

R. R. RACE,\* M.R.C.S., L.R.C.P.

(From the Galton Laboratory Serum Unit, Department of Pathology, Cambridge)

A predominance of homozygous RhRh fathers in families where an Rh-negative mother has borne children suffering from haemolytic disease of the newborn has been suggested by Race, Taylor, Cappell, and McFarlane (1943). An Rh-negative mother is more liable to be immunized when every pregnancy is Rh-positive and provides the antigenic stimulus, as it does with a homozygous husband, than when he is heterozygous RhRh and some of the children are positive and others negative. This being so, it is obvious that the proportion of homozygous fathers producing affected children will be greater than the proportion of heterozygous fathers. It can readily be shown that in a random sample of Rh-positive males about 3 out of 7 must be homozygous and 4 must be heterozygous.

Race and Taylor (1943) have described a serum which discloses the genotype of half the persons who are homozygous RhRh. This serum, called "St" from the first two letters of the donor's surname, agglutinates the blood of all Rh-negative rhrh and of all heterozygous Rhrh persons, but it fails to react

\* Working on behalf of the Medical Research Council.

with about 20% of bloods (St-negative) all of which must therefore be homozygous RhRh and represent about half the Rh-positive homozygotes—about 38% of the population. Race and Taylor pointed out that the extent of any preponderance of homozygotes among the fathers of erythroblastic children should be indicated by the proportion found to be St-negative. In 46 families in which the disease occurred and in which all the mothers were Rh-negative and had anti-Rh agglutinin in their sera, 18 of the fathers have been St-negative and 28 St-positive. If about half of the homozygotes are St-negative, then it appears that of 46 fathers about 36 were homozygous; these frequencies, compared with those expected in the general population, are:

	Observed St	Observed St -	Estimated Homozygotes	Estimated Heterozygotes
46 fathers	18	28	36	10
	Expected St	Expected St -	Expected Homozygotes	Expected Heterozygotes
46 random Rh+ men	10-11	35-36	20	26

and in that case the homozygous fathers would be  $\frac{36}{10} \times \frac{26}{70}$ —i.e., 4.68—times more dangerous than the heterozygotes. The difference in distribution among the fathers and the normal population is highly significant statistically. Again, in a normal population of 46 Rh-positive persons 10 or 11 are expected to be St-negative and about 35 St-positive; that 18 fathers were St-negative and 28 St-positive is statistically significant.

Further evidence of the preponderance of homozygous fathers in affected families is given by the results of more recently discovered tests which determine certain Rh genotypes. The inheritance of the Rh groups is determined by a series of multiple allelomorphs, and by the use of different sera from the mothers of erythroblastic babies the genotypes of about 80% of persons can be recognized. (See Race and Taylor, 1943; Race, Taylor, Boorman, and Dodd, 1943; Race, Taylor, Cappell, and McFarlane, 1944.)

Of the 46 fathers 38 were examined by tests which recognize the Rh<sub>1</sub>rh and Rh<sub>2</sub>Rh<sub>2</sub> genotypes. In the general population the frequency of Rh<sub>1</sub>rh is about 33%—that is, about 40% of Rh-positives. Of 38 Rh-positive fathers, therefore, 15 would be expected to be Rh<sub>1</sub>rh and 23 not Rh<sub>1</sub>rh. But only 5 fathers were Rh<sub>1</sub>rh—a highly significant departure from expectation, which shows a marked shortage of this commonest type of heterozygote. Thus:

	Rh <sub>1</sub> rh	Not Rh <sub>1</sub> rh
38 fathers: observed	5	33
38 random Rh+ men: expected	15	23

In 435 unselected donors the ratio of the genotype Rh<sub>1</sub>Rh<sub>1</sub> to Rh<sub>1</sub>rh was almost exactly 1 to 2; but of these 38 fathers 14 were Rh<sub>1</sub>Rh<sub>1</sub> and 5 Rh<sub>1</sub>rh—again a highly significant shortage of Rh<sub>1</sub>rh.

The tests on the last 18 of the 46 fathers made it possible to recognize the following genotypes:

	Rh <sub>1</sub> Rh <sub>1</sub>	Rh <sub>1</sub> Rh <sub>2</sub>	(Homozygotes)	Rh <sub>1</sub> rh	Rh <sub>2</sub> rh or Rh <sub>2</sub> Rh <sub>2</sub>	(Heterozygotes)
Observed	7	6	(13)	3	2	(5)
Expected	4	3	(7)	8	3	(11)

The serological tests do not yet differentiate between the genotypes Rh<sub>1</sub>rh and Rh<sub>2</sub>Rh<sub>2</sub>, but, assuming the two fathers in this group are heterozygotes, then there are 13 homozygotes and 5 heterozygotes, whereas 7 and 11 would be expected in the general population: the discrepancy is on the verge of statistical significance. The 18 fathers have 23 Rh<sub>1</sub> genes to 8 Rh<sub>2</sub> genes—practically the same ratio, 41 to 15, found in the general population. This suggests that both genes are equally effective in producing the disease.

It may be thought that the manner of ascertainment has been responsible for the high proportion of homozygous fathers found in our sample, and that the diagnostic support given by a history of more than one jaundiced baby may make a doctor the more likely to send us blood samples and thus

prejudice our series in favour of homozygous fathers. This difficulty can be overcome if we consider fathers of families in which only one child is erythroblastic. There are 26 such: 9 of them are St-negative—a proportion not very different from that found in the remaining families with 9 St-negative fathers out of 20. Twenty of the fathers of families with a single affected child were examined by the tests which recognize Rh<sub>1</sub>rh and Rh<sub>2</sub>Rh<sub>2</sub>, and they show a significant shortage of Rh<sub>1</sub>rh, there being only 2 instead of the expected 8, while the ratio of Rh<sub>1</sub>rh to Rh<sub>2</sub>Rh<sub>2</sub> is 2 to 7 instead of the expected 6 to 3.

### Conclusions and Summary

The findings reported prove that there is a marked preponderance of homozygous fathers in families affected by haemolytic disease of the newborn: the homozygote appears to be about four or five times more dangerous than the heterozygote. This predominance of homozygotes affects enormously the chances of Rh-negative, and therefore unaffected, children being born. The genotype of about three-quarters of Rh-positive people can be determined serologically, and unless it can be shown that the father is heterozygous in this way, or by his having an Rh-negative child or an Rh-negative parent, the prognosis is entirely unfavourable.

## Medical Memoranda

### Latent Malaria presenting as Anaemia

Anaemia is a well-known feature of malaria, both during the acute phase of the disease and in convalescence. Treatment by iron is not by any means always necessary, but in most cases is quickly curative. An anaemia, nevertheless, may occur which is both iron-resistant and susceptible to antimalarial therapy, at a time when the parasite would not normally have been suspected as the causative factor. Two such cases of anaemia are here reported. Response to antimalarial treatment was immediate and satisfactory in both cases.

#### CASE I

During Oct., 1942, this man had a first attack of clinical malaria which was apparently successfully cured by the usual course of treatment. Ever since then he had complained of cough, pains in the joints, and profuse sweats, and he was apyrexial. He was seen as an out-patient on Dec. 30—two months after his initial illness—when his condition suggested a blood count. This showed: R.B.C., 3,170,000; Hb, 70% (Sahli); C.I., 1.1; W.B.C., 5,100—polymorphs 38%, lymphocytes 56%, monocytes 6%.

He was admitted to hospital five days later. Detailed physical examination revealed a young man in poor condition and with marked pallor. Temperature 99°; pulse 80. Tongue furred; throat clear. Heart normal in size and position; rhythm regular. On auscultation there was a widespread systolic murmur, best heard along the left border of the sternum. B.P. 120/60. The lungs showed no abnormality. The liver was palpable and tender. The spleen was not palpable. Blood films for malaria parasites were persistently negative.

X-ray films of the chest showed no abnormality. On Jan. 1, 1943, a blood count gave: R.B.C., 3,640,000; Hb, 90% (Sahli); C.I., 1.2; W.B.C., 6,000 (polymorphs 53%, lymphocytes 42%, monocytes 3%, eosinophils 2%). Intensive iron therapy was instituted (ferri et ammon. cit. gr. 120 per diem). After one week the red cells had diminished by 20,000 and the Hb by 10%. Symptoms were not diminished, and his condition was unchanged. Some days later he suddenly developed an acute pyrexial illness, during which M.T. parasites were found in the blood film. Iron was discontinued and antimalarial treatment given. At the end of the treatment the red cell count had risen to 4,390,000, and when the patient was discharged it and symptom-free a few days later this number had reached 5,500,000, with 96% Hb and 12,200 white cells, although anti-anæmic treatment by iron had not been reinstituted.

#### CASE II

A prisoner of war, 42 years old, admitted to hospital on May 11, 1943, complained of weakness, headache, and slight diarrhoea. There was a history of ten attacks of malaria in the previous five years.

On examination the patient was found to be pale but not icteric. Temperature normal; tongue coated. Some petechial spots were

present on gums and palate. The chest was normal. The spleen was palpable and tender. Pathological examination of the stools showed no evidence of dysentery. In four days the stools were repeatedly normal and the blood count was: R.B.C., 2,900,000; Hb, 57%; C.I., 1.0; W.B.C., 13,000. Intensive iron therapy and liver diet for 16 days produced no beneficial effects—in fact, there was a diminution of 490,000 in the red cell count and 8% in the Hb estimation. His temperature remained normal, his spleen was palpable, and no malarial parasites were found in the blood films. Since neither symptoms nor anaemia had been improved by iron therapy and liver diet this was stopped, and replaced by a full course of antimalarial treatment. The response was immediate. By the end of the course he was symptom-free; the spleen was not palpable; and the blood count was: R.B.C., 4,350,000; Hb, 82%; C.I., 0.9; W.B.C., 5,800 (P. 69%, L. 22%, M. 6%, E. 3%).

British Military Hospital, Khartoum.

## Two Cases of Imperforate Anus

In view of the comparative rarity of the condition, perhaps the two cases here reported may be of interest in that they illustrate two of the different varieties of the condition.

### CASE I

The baby had been born precipitately 48 hours before I was called to see it by a district midwife, who informed me that it had vomited repeatedly and had passed no meconium since birth. On examination it was an apparently normal full-term child, weighing 5 lb. 7 oz., but obviously an ill one. Its temperature and pulse were normal, but the abdomen was somewhat distended and the child vomited every feed that was given. It was admitted to hospital the same day, and x-ray photographs confirmed the clinical diagnosis of imperforate anus. Operation was undertaken that evening and an attempt made to divide the septum which had been shown to separate the rectum from the anal canal. This, however, proved impossible owing to the narrowness of the orifice and the distance of the septum from the anus, so an iliac colostomy was performed. A considerable amount of fluid was found in the peritoneal cavity. There was a recurrence of vomiting later the same night and the stomach was washed out, but the child died in the early hours of the morning.

### CASE II

This child, with its mother, was transferred to the Northern Hospital from the hospital in which the birth had taken place; transference was for the mother's convalescence. Birth had been by forceps delivery, and the infant had apparently been considered quite normal and its condition satisfactory. It was apparently a 40-weeks baby, and weighed 8 lb. 1 oz. at birth. It was receiving three-hourly feeds at the breast. The day after arrival at this hospital the infant was obviously ill. Its weight had fallen to 7 lb. 5 oz., its colour was poor, and the abdomen was distended. On examination it was at once seen that no anal orifice existed. This fact had apparently been missed previously owing to the napkins having been stained with meconium, which, it now appeared, was being passed via the urethra.

Immediate operation was performed under ether anaesthesia and an attempt made to find the lower end of the bowel through a cruciform perineal incision, but it soon became evident that no rectum existed at all. While on the operating table meconium was passed from the penis. An iliac colostomy was therefore performed, but the child's condition continued to deteriorate and it died the same night.

At the necropsy there was complete absence of the rectum, and a fistula existed between the lower end of the bowel and the membranous urethra. A dissection of the affected organs was made and mounted, and subsequently accepted by the museum of the Royal College of Surgeons.

### COMMENT

The first of these cases illustrates the type of imperforate anus in which a complete membranous septum persists between the post-allantoic gut and the proctodaeum. Case II belongs to the group in which the original communication with the cloaca persists—associated, as is usually the case, with non-development of the post-allantoic gut.

I wish to record my thanks to Dr. A. G. Wilkinson for permission to publish Case I; to Dr. Björkgren under whose care Case II was admitted to this hospital and who diagnosed the condition; to Mr. W. Rothwell, who performed the operation and made the post-mortem dissection; and to Dr. G. A. Borthwick, medical superintendent, Northern Hospital.

Northern Hospital, N 21

IAN A. J. MCCREADY, M.R.C.S.

It is reported from Berlin that a single fruit of a specific Bulgarian white rose contains about 4,000 to 5,000 mg. vitamin C. This (according to *Svenska*, Aug. 24, 1943) is a sensational discovery, as hitherto the quantity of vitamin C in vitamin-bearing plants ranged from 400 to 1,000 mg. At the same time, a new method of vitamin extraction has been introduced in Bulgaria, and it is expected that this industry will revolutionize the economic life of that country. The dried seeds are to be compressed into tablets, each of which will contain 20 mg. vitamin C.

## Reviews

### MODERN STATISTICS

*The Advanced Theory of Statistics.* By Maurice G. Kendall, M.A. Volume I. (Pp. 457. 42s.) London: Charles Griffin and Co., 1943.

The 457 quarto pages of vol. I of Maurice G. Kendall's book bring back vivid memories to a reader whose statistical education began more than 40 years ago. Even at that time the mathematical literature of the theory of probability was already large; a good deal had been written which those whose formal education in mathematics had been elementary found difficult reading. But textbooks in the titles of which the word "statistics" or "statistical" appeared were descriptive and arithmetical rather than algebraical. In the 40 years general mathematical education has been improved. A youth who has reached the standard of a Higher School Certificate in mathematics may not have much more difficulty in reading Mr. Kendall's book than his father, or grandfather, with equivalent training, had with Todhunter's *History of the Mathematical Theory of Probability* and—this is the essential difference—will cover a much wider field of practically important knowledge.

The columns of a medical journal are not the proper place, even were the reviewer a proper person, for a critical analysis of a primarily mathematical treatise. But as the medical profession numbers in its ranks men of varied non-professional learning, and as statistical analysis has become an orthodox method of medical research, it is proper to indicate the scope of the book and the change in the intellectual attitude of statisticians which it illustrates. A reader of a mathematical book has two difficulties: the writer may assume knowledge of methods and results the reader does not have; he may use a notation or a calculus which is unfamiliar. In this book the difficulties are rather of the second than the first class. We think that an amateur who reads carefully a pamphlet by the late H. E. Soper entitled *Frequency Arrays* (published by the Cambridge University Press in 1922) would find Mr. Kendall's exposition easier to follow. We should add that Mr. Kendall follows the admirable example of Karl Pearson—viz., provides arithmetical examples wherever possible.

Comparing past with present, summarily, we may note that the great pioneers of half a century ago, particularly Karl Pearson, were empiricists in the best sense of the term. Their new methods were powerful instruments, but their logical justification of them was much less complete than we, their pupils, or perhaps they themselves, supposed. It is indeed certain that Karl Pearson did not suppose he had placed the method of moments upon a wholly satisfactory basis of mathematical logic, but his pupils were often free from doubts. A comparison of Pearson's article in *Biometrika* (1902, 1, 265) with Mr. Kendall's 4th chapter, especially pp. 105 *et seq.* shows how far we have travelled since 1902.

But that does not mean the debt to Karl Pearson is small and that those medical biometricians who "fit" by moments are wasting their time. A natural association of ideas leads one to compare the editorial on probable errors of frequency constants in the second volume of *Biometrika* (1903, p. 273), which was the model we admired 40 years ago, with Mr. Kendall's 9th, 10th, and 11th chapters. We know now, among other things, that it is not quite so easy to evaluate sampling moments as we had thought, and that moments are not the most useful functions to study. Here we might remark that a reader coming fresh to *k*-statistics would find a little book by the late P. A. Macmahon (*An Introduction to Combinatory Analysis*, C.U.P., 1920) helpful. Macmahon wrote this booklet (71 pages) as an introduction to his large treatise: the modern history of statistics shows how wise was Macmahon's own remark that "the theory of probabilities is to a large extent concerned with and dependent upon the enumeration of combinations subject to conditions, and almost every theorem in combinatory analysis has its application to that theory" (*Combinatory Analysis*, vol. I, p. vi). We are, however, diverging from the general to the particular. The remaining chapters of Mr. Kendall's book, treating of association

and contingency, product moment correlation, partial and multiple correlation, and rank correlation, will not be too hard reading for those who have had practical experience of the methods and already studied an elementary textbook.

While, as said at the beginning of this review, we have no pretension to give judgement on a work primarily addressed to a mathematical public, we have no doubt of its value and are sure that many medical statisticians who are not mathematical experts could read it with profit if they will take hints we have given as to preliminary study, and to read slowly. It is not a book for hasty perusal.

There is a good deal to be said for statistics, in the most general sense of the term, as a source of intellectual pleasure appealing to a wide range of tastes and natural aptitudes. To some its chief merit is as a method of research which can be applied without access to a laboratory; to others it is an opportunity to test imagination and a sense of logical consistency. Mr. Kendall appeals more to the second class; but students of the former class—no doubt a majority of medical readers—will find in the book danger signals intelligible enough even if the proofs that there is danger may be hard to follow. We wish Mr. Kendall equal success in the second part of his undertaking.

### STUTTERING

*Stuttering: Significant Theories and Therapies.* By Eugene F. Hahn (Pp. 177, 12s.) California: Stanford University Press, London: Oxford University Press, 1943.

This book consists of a collection of short essays or descriptions setting forth the views of numerous writers on the causation and treatment of stuttering. These writers include eighteen American authorities and eight European, among whom are Austrian, English, French, and German exponents. As each essay consists of about half a dozen pages and often less it is evident that the book does not lend itself readily to a review. There is, however, a large consensus of opinion that the underlying cause is some form of mental conflict, and that some form of psychological treatment is therefore a necessary basis to the successful management of such cases. On the other hand, there are those, such as Dr. Walter B. Swift, who seek a conscious process rather than the subconscious processes of the psycho-analysts as the cause, but all are agreed that stuttering is a neurosis. If it is permissible to mention a few of the essays which carry most conviction by their simple scientific approach to the subject, those by Dr. Meyer Solomon and Dr. Lee Edward Travis stand out prominently. This book should certainly be helpful to speech therapists who deal with stuttering, and its value is increased by the inclusion of a useful bibliography.

### INJURIES OF THE FACE AND JAWS

*Synopsis of Traumatic Injuries of the Face and Jaws.* By Douglas B. Parker, M.D., D.D.S. (Pp. 334; illustrated, 22s. 6d.) London: Henry Kimpton.

Now that so many American oral surgeons are with us in this country it is both interesting and stimulating to follow the progress of their maxillo-facial surgery and compare their technique with ours. The American doing this work is first and foremost a dental surgeon who has had a specialized training and experience in facial and jaw injuries and undertakes the operating, much of which in this country would be done by the plastic surgeon. Hence Dr. Douglas B. Parker's approach to the subject is that of the oral surgeon who takes full responsibility and charge of the patient.

This is a useful book for anyone who has had no previous experience in this branch of surgery, and it gives a sound introduction to principles employed in the treatment of these tragic injuries, without wasting space on the details and construction of the more complicated splints and methods of stabilization. Much of the terminology is different from ours, and such phrases as "automotive accidents" and "fistic encounters" may sound strange, but the text is clear and concise. The illustrations and diagrams are excellent, and should be better still in later editions when material from the present war can be added. The early chapters deal with anatomy and surgical technique, and the diagrams on suturing deserve special praise. The section on the stabilization and treatment of fractures differs little from that taught in this

country. We look forward now to seeing our American colleagues over here at work and will observe their maxillo-facial technique with interest.

### Notes on Books

*Methods for Diagnostic Bacteriology*, by ISABELLE G. SCHAUB and M. KATHLEEN FOLEY (Henry Kimpton; 18s.), is a useful bench book describing the methods employed at the Johns Hopkins Hospital. The second edition has been amplified by a chapter on the identification of pathogenic bacteria by their colonial characters; otherwise it follows the same plan as before, instructions being given first for the examination of various kinds of specimen, and later for the further study and identification of bacteria cultivated from them. Final chapters deal, as before, with serological methods and the preparation of culture media and stains.

The National Smoke Abatement Society has published in pamphlet form the *Proceedings of the London Conference, 1943*, on smoke prevention in relation to plans for post-war reconstruction. The price is 1s. and it is obtainable through booksellers, or direct and post free from the National Smoke Abatement Society, Chandos House, Buckingham Gate, London, S.W.1.

### Preparations and Appliances

#### ANAESTHETIC FACEPIECES: DEVICE FOR PROMOTING AN AIR-TIGHT FIT

Dr. H. J. V. MORTON writes from Hillingdon County Hospital, Middlesex:

The device represented in the accompanying sketch assists very considerably in procuring an air-tight fit between the anaesthetic mask and the patient's face. It can be adjusted to bring pressure to bear at the points where leakage usually occurs, and is particularly useful if one is forced to use an inefficient facepiece or when a patient's physiognomy is unusual.

The method of use in conjunction with a standard Clausen's harness is clear from the diagram. Two studs in the harness make for increased adaptability.

The usefulness of this simple device in closed-circuit anaesthetics, especially when cyclopropane is being used, is evident. In the majority of cases the tension on the rubber band also assists in "holding up the chin." It should always be used with an appropriate airway in position.

The appliance can be obtained from Medical and Industrial Equipment Ltd., 12, New Cavendish Street, London, W.1.

## NEUROSIS AFTER WAR SERVICE

## REHABILITATION AND RESETTLEMENT

The eighth medical conference of the Ex-Services Welfare Society was held on Feb. 8, with Lord HORDER presiding in the morning and Prof. J. LE FLEMING BURROW in the afternoon. A general discussion on neurotic illness in men discharged from the Services and their settlement in industry was opened by Col. THOMAS TENNANT of St. Andrew's Hospital, Northampton. Experience had shown, he said, that certain types of neurotic and even of psychotic illness responded to a comparatively short period of treatment, while in other types equilibrium could be maintained only by a long period in a sheltered environment. The disadvantage of institutional treatment was that the patient was separated from his home, supposing his home environment to be favourable. If the plans suggested for the development of post-war psychiatry materialized, neuro-psychiatric units would be established in many parts of the country, and might be used in the same way as the Maudsley in London.

Dr. AUNREY LEWIS said that the problem of the neurotic or psychotic individual should not be separated from that of physical disablement. The neurotic man should be regarded as having only a temporary disability, and every effort should be made to avoid conflict between him and the other men with whom he associated in industry. There was some foolish prejudice against neurotics, and they, more than any other disabled type, were open to the suspicion of malingering; they were also more liable to recurrence after apparent recovery. Not only were more psychiatrists needed, but a better distribution of those available.

## Absorption into Industry

An interesting contribution was made to the conference by Dr. E. MOIR (senior medical officer, Ford Motor Company), who said that his experience of the absorption of psychotic and neurotic ex-Service men into industry led him to feel that they should be put to work in normal surroundings under suitable supervision as soon as possible. Sheltered industries in some cases were necessary, but they tended to become sick bays. They reminded the patient that he was still a sick man. His case called for the united efforts of the psychiatrist, the general practitioner, and the industrial medical officer. In the Tomlinson report the works doctor was mentioned only once, and then by analogy, and the general practitioner was, not mentioned at all. It would be well if every G.P. held a part-time industrial post. An eminent psychiatrist had said that he could discharge half his patients if their home conditions were satisfactory, and it was the G.P., knowing the home conditions, with the industrial medical officer, knowing the working ones, who together should encourage them along the path of recovery.

Brig. J. R. REES said that the problem called for the sociologist as well as the clinician. He addressed himself in particular to the question of pensions. There must be a certain number of cases in which, although the man might have had a predisposition before entering the Service, the excessive strain of warfare had made his condition really attributable to the Service in the sense that his breakdown would never have occurred had he remained in normal surroundings. In such cases a pension might legitimately be granted, but he was sorry that it should be necessary even in those, because pensions were extremely bad for the neurotic case. Dr. STRÖM-OLSEN deplored the dearth of social workers in association with psychiatric clinics.

Dr. J. F. E. PRIDEAUX (Ministry of Pensions) said that, taking the cases which were regarded as true war neurosis in the last war—cases in which there had been no predisposition or only a slight one—87% came off the pension list within two or three years after the armistice. He felt that such men could be reabsorbed into industry if the proper steps were taken. There was no doubt that the pension was the worst kind of "therapeutic instrument," as anyone who had treated side by side the serving soldier and the pensioner for the same kind of ailment would agree.

Dr. LOUIS MINSKI pointed out the virtual impossibility of the settlement of a patient in industry so long as his domestic

problems were agitating him. The domestic merited as much attention as the industrial side. He also spoke of the need for the employment of a welfare officer with some psychiatric knowledge by every firm which absorbed such men into its labour force. Col. A. A. W. PÉTRIE referred to the vicious circle created when men were discharged from mental hospitals with 100% disability pension; when, on their gradual recovery, the pension was cut down they became the subject of an acute depressive attack and had to return to the mental hospital.

## A Single Problem

Mr. GEORGE TOMLINSON, M.P., Parliamentary Secretary to the Ministry of Labour and National Service, addressed the conference. Rehabilitation and resettlement, he said, were a single problem; hitherto the two things had been dissociated. He felt that unless the stigma which still clung to the mental hospital could be removed, patients should only be allowed to go there as a last resort. In the rehabilitation of a certain type of neurotic patient the attitude of his employer and of his fellow trade unionists was probably more important than anything else, and in spite of the fact that a Bill had now passed through the House of Commons providing on a compulsory basis for the employment of disabled persons, it was just as essential as ever to get the understanding and co-operation of both sides in industry. The object of his committee (the Committee on the Rehabilitation of the Disabled, of which he was chairman) had been to ensure that the disabled person should be able to obtain his job and keep it on his merits as a worker in ordinary competition with his fellows. That was the only rehabilitation which was really worth while. He sympathized with the protest made by one speaker in the conference against the assumption that the only employment for which a one-armed man was fit was door-keeping or lift-attending, but at the same time it was as well to remember that the loss of an arm did not make a man a genius; he might only be fit for door-keeping or lift-attending if he had retained both arms. Mr. Tomlinson as a trade unionist paid a tribute to the general body of doctors. There had been a good deal of recent trouble over certification, but he felt certain that in many cases the doctor had given a certificate which perhaps was not very explicit and might include some such phrase as "general debility," because he knew that he could probably arrest what was developing in the patient if he could put him "on the club" for two or three weeks.

Prof. BURROW said that part-time help among civilian by psychiatrists now serving in the Forces would be of very great assistance in the rehabilitation of the cases with which civilian doctors were now called upon to deal. There were too few psychiatrists to give the necessary individual treatment in cases of neurosis.

## TUBERCULOSIS IN INDIA

The fourth annual report of the Tuberculosis Association of India states that there are now 112 tuberculosis clinics and 66 tuberculosis hospitals and sanatoria in that country, with a total of over 4,000 beds. In addition there are more than 1,200 beds for tuberculous patients in general and isolation hospitals, and over 700 for tuberculous convicts in prisons. One of the most noteworthy institutions in India is the New Delhi Tuberculosis Clinic; at which, during the latest year, 2,240 persons were examined, nearly half of whom were found to be suffering from the disease. The Lady Lialitigow Sanatorium at Kasauli, with 136 beds, is also doing excellent work and is becoming known, the number of applications for admission greatly exceeding the number of beds available. Patients are admitted to this institution from all parts of India without distinction of race or caste. There are now affiliated with the Tuberculosis Association fourteen Provincial and five State associations, the latest to be formed being in the States of Hyderabad, Bikaner, and Rampur.

On the basis of the treatment of 50 typhus cases with convalescents' blood, Pfeiffer and Gauserky (*Klin. Wschr.*, 1943, 22, 48) state that favourable results are produced by it. The principal effects are shown in a shortening of the period of fever and less severe central nervous symptoms. The mortality in cases which have been transfused is less than in those without transfusion. It is sufficient, they state, to make a single transfusion of 200 ccm of convalescent blood, and this ought to be done at the beginning of the case.

## BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 26 1944

## THE WHITE PAPER

By now all doctors in this country will have some idea of the proposals in the Government White Paper on a National Health Service, published last week<sup>1</sup>; and soon everyone will receive a copy. It is hoped that everyone will read and re-read this so as to grasp in both broad principle and narrow detail just what is the very fully considered view of the Government on an issue of first importance to the people of the country and to the medical men whose task it is to care for them in health and in sickness. It should be made clear at the outset that the White Paper, which is designed to meet the demand of the Beveridge report for a comprehensive medical service is "concerned exclusively with the direct services of personal health care and advice and treatment." It is not concerned with the environmental health services, nor with the school service, nor with the industrial medical service. The main reason for change," it is stated, "is that the Government believe that, at this stage of social development, the care of personal health should be put on a new footing and be made available to everybody as a publicly sponsored service." It is considered that the people of this country should come to look upon the public provision of a comprehensive personal health service as much a communal provision as the provision of good highways or a clean and safe water supply. The service is to be available to everyone in the community who wishes to avail himself of it, and it is to be free, payment for it coming out of taxes, local rates, and the insurance contribution under the social security scheme. It is to be complete. The service is to be founded on the "family doctor" idea; there is to be freedom for people to use or not to use the facilities made available; there is to be no compulsion into the new service either for patients or for doctors; there is to be freedom for entering into private arrangements at private cost; the patient is to be free to choose his doctor. With these general principles the profession are in agreement. The idea of a comprehensive service based on the personal relationship between patient and doctor, with no financial barrier between it and the patient, is one which the B.M.A. has consistently held before the profession.

The White Paper, written in attractive and lucid English and free from verbal ambiguity, recognizes that "there is a certain danger in making personal health the subject of a national service at all. It is the danger of over-organization, of letting the machine designed to ensure a better service itself stifle the chances of getting one." It recognizes that the object of organization is to ensure that the service is available, and that it is a good service. Organization is a means, and not the end. The

form of central organization favoured by the Representative Body is not accepted, and the reasons for continuing the responsibility to Parliament of a Minister, the head of a Department of Health, are briefly given. For Scotland the responsibility would be that of the Secretary of State. At the side of the Minister there will be set up a statutory Central Health Services Council, which will have no executive powers but the duty to advise the Minister on the technical and professional aspects of the service. It will also have the power to initiate advice on matters it holds to be of importance. The Minister will submit an annual report to Parliament on the Council's work. It is proposed that this body shall be made up largely of medical men, and that experts' advice on the other aspects of the health service must also be available, through, for example, hospital administrators, nurses, dentists, pharmacists. It is not contemplated that the work could be regularly done at single meetings of the full Council, but that it should establish small groups or subcommittees out of its provisional 30 or 40 members, who will be appointed by the Minister in consultation with professional and other organizations. The Council will elect its own chairman and regulate its own procedure, and will be provided with a secretariat. At the periphery there will be corresponding Local Health Services Councils.

The other central administrative structure is the Central Medical Board, small in size, composed mainly of members of the medical profession, some giving the whole of their time to the work and others part of it, acting under a permanent chairman, and working under the general direction of the Minister. The Central Medical Board will be an executive body. It will conduct the day-to-day central working of the public general practitioner service; will be the body with which the practitioner makes and ends his contract; will be the agency through which young doctors will obtain appointments as assistants; will control the distribution of general practitioners in accordance with population needs; will act as a sort of central bureau for giving advice and assistance to doctors in the public service; will arrange for postgraduate and refresher courses; and will be the central body and clearing house to which the new Joint Authorities will make known the medical needs of their local areas. It is plain that this small central body established in the Ministry of Health will have very important and powerful functions in relation to the conduct of medical practice.

As it is proposed that the general practitioner service is to be administered centrally, while the hospital service is to be administered locally, we shall first of all briefly review the proposals for the general practitioner service before discussing local administration. The report barely glances at the National Health Insurance scheme. It is allowed to pass with a few lines of obituary notice, and with it go the Insurance Committees. The White Paper gives reasons for not meeting the need for a comprehensive service by extending the panel system "to the whole population and expanding it to include consultant and specialist services." The first reason given is that at present there is no effective way of ensuring a proper distribution of doctors. The second is that developments

<sup>1</sup> A National Health Service, Cmd. 6502. H.M. Stationary Office. (J.S.)

of modern medicine "point the way to changes which need encouragement and experiment in any future service." As already stated, the doctor in the new general practitioner service will be in contractual relation with the Central Medical Board, which will be responsible for paying him. This board will take over most of the functions of the Insurance Committees, and will "discharge many of the minor day-to-day functions through a local committee or similar agency, on which there will be included members of the local authority in each area." The complete medical needs of any area will be determined by the new Joint Authorities of county councils and county borough councils which will administer the area hospital service. It would be for the Central Medical Board to act on the advice thus presented to it. The local Joint Authority will have to "provide for the linking of general practitioners . . . with a hospital, consultant, and other services in the area."

The Government put forward proposals for two kinds of general practice—namely, "grouped general practice" and "separate general practice." The new service is to be designed so as to give full scope for trying out the method of organizing medical practice by groups of doctors either in the special premises of a health centre or without such special premises—the latter presumably means on the basis of multiple partnership. It recognizes that experiment with different types of centre is necessary, and regards the object to be "to provide the doctors with first-class premises and equipment and assistance and so give them the best facilities for meeting their patients' needs. The doctors will thus be freed from the necessity to provide these things at their own cost." The general scheme is to make available individual consulting rooms and space for simple laboratory work, for nursing and secretarial staff, recovery and rest rooms, facilities for minor surgery, and so forth. These centres are first to be introduced in selected areas, and it is observed that a big factor will be the wish of local doctors to bring their work into the new centres; "but in the last resort the decision will rest on the requirements of the public interest." If the new Joint Authority decides that a health centre is necessary it will be the responsibility of the individual county or county borough council to provide it. Therefore the appointment of a doctor to the health centre will be made jointly by the Central Medical Board and the local council which administers it. The local council will provide the premises, the equipment, and the ancillary staff. "It seems fundamental," the Paper states; "that inside a centre the grouped doctors should not be in financial competition for patients. All the practical advantages of the centre . . . will be, under a system of a salaried team, at the disposal of the group in whatever way they like collectively to arrange. . . ."

In the "separate" general practice envisaged it is proposed to retain the general framework of the National Health Insurance scheme. Practice will be conducted as at present, but the doctor "will be backed by the new organized service of consultants, specialists, hospitals, and clinics." He will be paid from public funds on a capitation basis, but it is considered that in some circumstances

"it will be possible to remunerate the practitioner on a salaried or similar basis if he so desires." If a practitioner wishes to take over an existing public service practice or to set up a new one he must first seek the consent of the Central Medical Board, which may withhold this if it thinks that there are enough doctors in the area, and that other areas need more doctors. "The Board will thus be able to help the new Joint Authorities which, in their general concern with the health services of their area, will turn to the Board to encourage or discourage any further increases in general practice in the area." The Government makes the welcome proposal that newly qualified doctors leaving hospital should first of all go through an apprenticeship as assistants to more experienced practitioners, either at a health centre or in a separate practice. "The Board must also be able to require the young doctor during the early years of his career to give his full time to the public service where the needs of the service require this"—a requirement which seems to conflict directly with the general principle of "no compulsion into the new service, either for patient or for doctor" (our italics). It is recognized that the adoption of the White Paper proposals will destroy the value of some existing practices, and that compensation for this must be paid. An "efficient super-annuation system" is looked upon as a part of the health centre organization, but as something more difficult to institute for doctors in the separate practices scheme.

The Government intend to base the local administration of the new service on existing county and county borough councils. In most cases suitable hospital areas will be larger than the areas controlled by existing major local authorities. It is therefore proposed to combine existing county and county borough councils in joint boards for the larger hospital areas yet to be defined. In some cases an individual council may have under its jurisdiction a large enough hospital area, and therefore will remain unchanged. The new Joint Authority, as already mentioned, will have the duty of surveying the complete health needs of the area under its control. Just as there is to be a Central Health Services Council constantly advising the Minister, so are there to be Local Health Services Councils advising the new area authority. The Local Health Councils will advise on all matters referred to them by the Joint Authorities or other local authorities in the area, and also will have the right to initiate advice and to submit their views both to the local authorities and to the Minister. Once local needs are determined, the Joint Authorities will be to provide hospital services through the municipal institutions owned by them (and previously owned by the constituent councils), and through the voluntary hospitals the aim being to make each area as self-sufficient as possible. Sanatoria, fever hospitals, and mental hospitals will be transferred to the new Joint Authority, which, too, will take over those clinic services essentially of the nature of out-patient units—for example, tuberculosis dispensaries, mental clinics, and cancer diagnostic centres. The Government wish to make it possible for the voluntary hospitals to take their part in the service without losing their identity. "If once," it is stated, "the situation were to arise in which the whole cost of the voluntary hospitals

part in the public service (a service designed for the whole population) was repaid from public money, or indeed in which it was recognized that public funds were to be used to guarantee those hospitals' financial security, the end of the voluntary movement would be near at hand." The Joint Authority will contract with the individual voluntary hospital for services rendered in the public scheme, but it is not proposed that the sum paid should be assessed "as a total reimbursement of costs incurred." There is a need for more consultants distributed more widely throughout the country. The general practitioner will secure expert advice for his patient through the consultant employed by the hospital. While it is recognized that the ultimate responsibility for making hospital appointments must rest with those who conduct its affairs, some kind of external appointment machinery for the purpose of making recommendations is thought advisable in order to avoid "the danger of in-breeding." Another aspect of the new hospital service is a hospital inspectorate, composed of "a team of highly qualified medical men," not necessarily employed whole-time on this work. It would seem that the provision of a free service will bring to an end that highly valuable feature of our hospital service—the contributory scheme.

A much fuller survey of the White Paper appears in this week's *Supplement*, but the above summary will provide, it is hoped, some idea of the Government's scheme for a comprehensive personal health service made freely available to every person in the country who wishes to take advantage of it. There are many points of detail which are clearly controversial, and on which the Government expect to be challenged in discussion with professional and other bodies. Certain broad general conclusions may, however, be drawn at this stage. Throughout this well-written and for the most part unambiguous report is a clear recognition of the realities of the present situation. Even if it were agreed that a general practitioner service based on a health centre was the most desirable way of conducting the work of the family doctor, and even if it were agreed just what was the most suitable form for these centres, it would obviously take a long time before they could be set up even in the more densely populated areas of the country, and it would obviously be long before there were enough doctors available to man them throughout the country. Hence it is clear that in the meanwhile "separate general practice" would have to be carried on. For the moment, then, those who are opposed to the idea of a whole-time salaried State Medical Service have had their fears allayed. But it is important to recognize in the White Paper the unmistakable direction in which the mind of the Government is moving—and that is towards the institution of a whole-time salaried medical service, with the proviso that private practice shall not be denied to those who want it and that doctors in the public service may provide it. It would seem evident that the person who is paying for a free medical service through central taxation, local rates, and a social security contribution may find that private practice loses much of its attraction even if he can afford it. Similarly it would appear that private benefactions and contributions to

voluntary hospitals, and certainly financial support through contributory schemes, will begin to dry up. It is difficult to see how, in the kind of evolutionary changes which are so persuasively outlined, private practice as we know it to-day can survive as much more than a shadow of itself. There are parts of this report which will need careful scrutiny before their implications can be fully understood. For example, it does not seem to be intended that health centres should be really experimental in the early stages. They seem to be wanted, at least by the authors of this report, not so much for what they may be as for what they make possible—first steps towards State control and salaried employment. Again, if only practitioners entering health centre practice are to be compensated the result will be an immediate fall in the value of all practices. The report, having stated that the Central Medical Board should have power to prevent doctors entering an "over-doctored" area, goes on to suggest that no one should practise anywhere without first obtaining permission of the Board—a civil service structure which is to have power to direct newly qualified practitioners to whole-time public service. There is more than a hint here of authoritarianism. If this is to be read as a way of introducing a salaried medical service the proposal will be resisted to the full. In its early pages the White Paper enunciates principles which, to a great extent, have long been accepted by the medical profession. The profession will have few points of disagreement with the Government if these principles find expression in details of organization. If the discussions and negotiations are permeated by the spirit of the principles enunciated by the Government on page 47 of the White Paper, we believe it will be possible to evolve a comprehensive medical service on the basis laid down. But we detect a thread of argument and development leading in a direction which the profession refuses and will refuse to follow—that of whole-time salaried service under the State. If this interpretation is correct, it is useless to deny that there is trouble ahead.

### NUTRITIONAL NEUROPATHIES IN SPAIN

The tragic civil war in Spain produced famine conditions throughout the country. The greater part of the population of Madrid lived from August, 1937, till February, 1939, on such meagre rations as 1,060 calories a day and 34 g. of protein, of which only 22% was of animal origin. It is not surprising that an "epidemic" of nutritional deficiencies developed. The diet was especially low in the vitamins of the B complex, and caused deficiency symptoms which could be traced back to their lack. Peraita<sup>1</sup> reports his experiences of these years in Madrid, especially of the winter months in 1937-8, when many patients suffering from pellagra with psychological disorders were observed. The most interesting part of his observations is the description of neurological symptoms without pellagic skin lesions. Peraita was able to classify these cases into distinct groups; according to his view they are clearly related to a deficiency of the vitamin-B<sub>2</sub> complex. Under the difficult conditions of those days he was

<sup>1</sup> *Arch. Psychiat. Nervenkrankh.*, 1942, 114, 611.

able to study 300 patients suffering from various symptoms of vitamin-B<sub>2</sub> deficiency, and treat them so far as his limited medical resources allowed. One-third of the patients had psychological disorders; another third, apart from neurological symptoms, also had pellagic lesions of the skin. It is, however, the last third of the patients, comprising 98 cases, which he deals with in greater detail. These patients had neurological symptoms only and no skin lesions. Females predominated in a ratio of 4:1, persons of 40 to 60 years of age being in the majority. Peraita classifies this group as follows: paraesthetic syndrome, paraesthetic-causalgic\* syndrome, retrobulbar neuritis, funicular myelopathy, cochlear neuritis, mixed forms, and transitional forms, leading to the classic picture of pellagra. Similar symptoms were also observed in conjunction with characteristic pellagrous skin lesions.

The paraesthetic syndrome started often as tingling sensations in the distal parts of the toes and round the bed of the nails, and later spread to other parts of the foot. There were patients who suffered from similar sensations in their hands. A more serious disturbance was a very painful dysaesthesia, the patient suffering from pains similar to those described after injury of peripheral nerves (the so-called "paraesthetic-causalgic syndrome"). Special sensory disturbances, such as feeling of "cold and wetness" of the feet, burning sensations, and so on, were described. In the group classified as "funicular myelopathy" the symptoms were those due to damage of the posterior sensory spinal tracts, such as absence or diminution of the vibratory sensation and ataxia of a pseudo-tabes type. Little or no disturbance of the function of the efferent nerves was noted. The ankle- and knee-jerks were rarely diminished, but more often increased. Other symptoms were of a general character, including weakness, inertia, depression, "neurasthenia," and disturbances of sleep and of the heat regulation. Disturbances of bladder function appeared as a "miction impérieuse," polyuria, nycturia, to a complete paralysis. Many of Peraita's patients had a generalized hypohidrosis. Amenorrhoea or oligomenorrhoea was a constant finding. Erythema pernio, erythromyanosis crurum puellaris, and other trophic disturbances were seen, and responded well to dietetic treatment. All these changes could be brought to a common denominator—namely, to changes of the sensory and neuro-vasomotor system of central or peripheral type.

Treatment with yeast led to recovery. On the other hand, administration of crystalline vitamin B<sub>1</sub>—possible in only a few patients because of limited supply—did not cause the same rapid improvement as regular dosing with dried yeast. For these and other reasons, among them the clinical picture, Peraita suggests that the symptoms described are due not to a vitamin-B<sub>1</sub> deficiency but to a deficiency of the vitamin-B<sub>2</sub> complex. He groups them all under the heading of pellagra, which he prefers to call Casal's disease, since the term "pellagra" is associated with the characteristic lesions of the skin, colitis, and other typical symptoms which were observed in Madrid in only relatively few cases. Peraita admits that the few patients whom he treated with pure nicotinic acid did not respond so well as to yeast therapy, although the typical pellagic lesions were cured. The neuropathies described might be

due to deficiencies of other members of the vitamin-B<sub>2</sub> complex, but riboflavin proved to be therapeutically inefficient. The significance of Peraita's findings is obvious.

The cruel involuntary "experiment" of the dimensions experienced in Spain provided evidence of types of neurological disorder caused by nutritional deficiency of some sort or another. This same "experiment" is, unfortunately, to be expected on an even larger scale in Europe after the war. The appearance of classical pellagra in Madrid, where the population never ate maize, put nicotinic-acid deficiency on a firm aetiological footing: quick response to treatment with nicotinic acid clinches the matter. Peraita's clinical classification brings some kind of order into the tangle of the symptoms met with, and will certainly help prospective workers in the nutritional field in post-war Europe. It may, however, be an advantage to dissociate these nutritional neuropathies from the classical picture of pellagra, the clinical symptoms of which clear up with nicotinic acid. Further studies will show beyond doubt which of the factors of the vitamin-B complex is responsible for the various symptoms described by Peraita. Meanwhile we must rope them in under some such general description as "nutritional neuropathies due to vitamin-B-complex deficiency," realizing that such syndromes will complicate the well-known "classical" nutritional deficiencies, one of which is pellagra. This is important, apart from anything else, because symptoms like those described by Peraita have been ascribed to vitamin-B<sub>1</sub> deficiency.<sup>2</sup> A beneficial effect of coenzyme (thiamine pyrophosphate) on neuropathies of the motor and sensory nerves associated with pellagra has been reported by Lewy, Spies, and Aring.<sup>3</sup> Similar scattered reports of the effect of vitamin B<sub>6</sub> and pantothenic acid on certain neurological and psychological disorders in pellagra have also appeared, but so far have not been confirmed. It will be the task of workers on post-war relief in Europe to ascertain more critically and clearly whether deficiencies of any of these members of the vitamin-B complex play a significant part in the causation of disease in man and are responsible for some of the symptoms described by Peraita.

### THE DECLINE OF AIR-BORNE INFECTIONS

It is a good thing from time to time to sit down and consider in the broadest and most general way what we are trying to do by our efforts to combat disease. Anyone who has reflected in this way about infectious disease must have grasped the fact that two policies are being pursued, either of which if completely successful would remove all need for the other. They are immunization and the elimination of the micro-organism—that is, rendering the individual resistant to infection, or ensuring that he shall not encounter it. The merits of these two policies are among the very large questions discussed by Dwight O'Hara in his monograph entitled *Air-borne Infection: Some Observations on its Decline*,<sup>4</sup> a slim volume published by the Commonwealth Fund in which the reader will find much food for thought. The author's chief raw material is the mortality statistics of the State of Massa-

<sup>2</sup> N. Jolliffe in *The Biological Action of the Vitamins*, edited by E. A. Evans, 1942, p. 44, Chicago.

<sup>3</sup> *Amer. J. med. Sci.*, 1940, 199, 840.

<sup>4</sup> Oxford University Press. (8s. 6d.).

chusetts since 1900, and his text is printed on the dust-cover—a graph showing a steady decline in the annual deaths from each of four principal diseases of the respiratory tract. That the main cause of this happy decline is improved standards of living—better housing and better food in particular—rather than the efforts of the hygienist and immunologist, is a conclusion perhaps unpalatable to some branches of medical science but nevertheless inescapable. The choice between immunization and the elimination of infection is a problem to which the author gives a qualified answer: it depends very much on the infection. In general, immunity is the more reliable safeguard; but both methods should be employed, and there is an optimum point for each disease at which they should be balanced. The whole idea of any policy of elimination, however, seems to be undermined by the author's ideas about cross-immunity. He regards loss to industry by the common cold as time well spent, since but for this the population would become susceptible to something worse: colds "keep us from becoming immunologically soft." This is a doctrine of profound importance, amounting to a confession that complete and perpetual health is an impossibility. There are other somewhat speculative judgments. Not everyone, for instance, will agree with the author's condemnation of using convalescent serum to modify measles in a healthy child, and is it generally agreed that a cold-virus collaborates with the pneumococcus in initiating the attack of lobar pneumonia? The statistical information on which this monograph is based is singularly complete and embraces many points of interest, such as the high frequency of pneumonia among hospital interns, particularly on the medical side. The author writes interestingly and sometimes vividly. Thus, in his words, a community shielded from infection acquires "a susceptibility which has some of the qualities of gunpowder." Of neglect of opportunities for health he writes: "Nature does not discriminate between those who are unable and those who are unwilling." This thoughtful and far-seeing essay on a major problem of public health should be widely read, not only for the information and deductions which it contains but as an instrument for enlarging the vision.

#### PROBLEMS OF AGEING AND CARE OF THE AGED

The Nuffield Foundation Trustees (in development of one of the objects specified by Lord Nuffield) are undertaking a survey of the problems of ageing and the care of old people. The Ministry of Health and the Assistance Board have warmly welcomed the proposal and will co-operate in the conduct of the survey. The object is to collect and collate as much information as possible with regard to: (1) The problems—individual, social, and medical—associated with ageing and old age. (2) The work being done by public authorities and voluntary organizations, and the public and private resources that exist, for the care and comfort of old people in Great Britain. (3) The provision made for old people in those countries which have given special consideration to these problems. (4) Medical research on the causes and results of ageing. (5) The lines on which action might usefully be taken in the future by public authorities and private organizations, including the Foundation. The chairman of the Survey Committee is Mr. B. Seebohm Rowntree, and the medical members are Dr. A. D. Briggs, medical superintendent, Stobhill Hospital, Glasgow, and Dr. Aubrey Lewis, director of clinical research, Maudsley and Mill Hill Hospitals. Questions of medical research will be considered by a special subcommittee, consisting of Dr. A. Greig Anderson,

physician, Aberdeen Royal Infirmary; Dr. A. D. Briggs; Dr. Aubrey Lewis. Dr. A. S. Parkes, F.R.S., National Institute for Medical Research, Hampstead; and Dr. J. H. Sheldon, hon. physician, Wolverhampton Royal Hospital. The secretary to the Survey Committee is Mrs. N. M. Windett, B.Sc. (temporary address: 73, Great Peter Street, S.W.1). In questions of ageing and the care of the aged there is lack of collated information of a comprehensive and authoritative nature. This militates against due appreciation of the problems and hinders the search for adequate solutions. The survey now being undertaken should contribute to a better understanding of a social problem which will inevitably become more prominent in public thought and policy. It will also give the Nuffield Foundation a basis upon which to decide its future action with regard to the care of old people.

#### CENTENARY OF THE MEDICAL DIRECTORY

In the year 1825 John Churchill, grandfather of the present managing director of J. and A. Churchill Ltd., Mr. A. W. Churchill, M.A., started his business career. Among his early publishing activities were the famous series of manuals on medical and surgical subjects. The first of these was entitled *The Anatomist's Vade Mecum*, by Sir Erasmus Wilson, and was followed by Sir William Fergusson's *Manual on Surgery* and by many others. These proved to be the forerunners of the many well-known medical and scientific books of the house of Churchill which have been used by generations of students and practitioners. In 1845 John Churchill published the first edition of the *Medical Directory*. It was a small volume of 700 pages in foolscap octavo size. The 1944 edition is a large royal octavo volume of over 2,500 pages, and contains 70,000 entries (price 63s.). The rapid growth in numbers of the medical profession and the geographical distribution of its members are clearly indicated in tables on the reverse of the title-page. From its first issue the purpose of the *Medical Directory* has been to set out in concise form the professional status of the doctors whose names appear therein. Details are given of the names, addresses, qualifications, appointments, and publications of medical men and women practising in the British Isles, over-seas, and in the Forces. Particulars are also furnished regarding universities, colleges, hospitals, and other institutions, together with miscellaneous data of interest and value to the profession. The centennial volume published this week contains 68,235 names divided as follows: London, 9,366; Provinces, 29,975; Wales, 2,288; Scotland, 7,675; Ireland, 4,693; Abroad, 11,229; Services, 3,027. It also includes near the end of the text the names of 2,682 practitioners who have been temporarily registered in Great Britain in pursuance of an Order made under Defence Regulation 32B. The Late List of new names and changes of address, etc., has been moved this year to a more convenient position—immediately in front of the London section. The publishers are to be congratulated on the hundredth issue of a professional book of reference which in its comprehensiveness has no rival in any other country; moreover, its accuracy has become proverbial. They can justly claim that the modest first edition of the *Medical Directory* was in fact one of the earliest steps towards the co-ordination of all qualified practitioners in the British Isles.

Guy's Hospital has lost two distinguished members of its consulting staff: Dr. John Fawcett, for many years physician to the hospital, and Prof. John William Henry Eyre, M.D., formerly bacteriologist. Dr. Fawcett died in a London nursing home on Feb. 18, and Prof. Eyre at Ivy Hatch, near Sevenoaks, on Feb. 17.

## Nova et Vetera

### MEDICINE IN THE OLD MERCHANT NAVY

At the February meeting of the Section of History of Medicine of the Royal Society of Medicine, with Sir WALTER LANGDON-BROWN presiding, Prof. J. A. NIXON gave a discourse on health and sickness in the Merchant Navy up to the end of the Napoleonic wars.

He dated the beginning of the Merchant Navy to John Cabot's discovery of Newfoundland. Before the discovery of the New World and the undertaking of long voyages by English seamen, the problems of disease and sickness at sea were very much the same as those on land. With long voyages came the need for ship surgeons. In Sebastian Cabot's ordinances for his intended voyage to Cathay in the middle of the sixteenth century there was no mention of surgeons being carried, but in a voyage to the East Indies in 1552 there was a captain's instruction to furnish 200 able persons for the three ships, the persons to include chirurgens. In the last voyage of Drake and Hawkins to the West Indies in the fifteen-nineties, while wintering at Grand Canary, they were attacked by the natives and the surgeon of the ship was taken prisoner. The charter granted to the Barber Surgeons of London by Charles I in 1629 instructed them to examine sea surgeons and to compel any ship sailing from the Port of London to carry a surgeon. If that instruction was literally obeyed, said Prof. Nixon, we had evidently dropped back since those days.

The next legislation for carrying a surgeon on board ship seemed to have been in the 26th year of George III, when the Arctic whalers were compelled so to do by the Act regulating the Greenland fisheries. In 1769 it was enacted that no ship should sail unless there was at least one surgeon on board who could produce a certificate of having passed his examination at Surgeon's Hall or at some public or county hospital or the Royal College at Edinburgh. In the 43rd year of George III vessels carrying 50 persons were required to include a surgeon. There was also an instruction that the journals of such surgeons should be sent to Dr. Hunter (Prof. Nixon thought this was William Hunter) of Charles Street, St. James's. Examination of the journals showed that cholera was classified among nervous diseases.

Of James Cook and his efforts to overcome scurvy Prof. Nixon had a poor opinion. He based his criticism on a letter written by Cook to Sir John Pringle which was read by him at the Royal Society in 1775. In this letter Cook said that he had no great opinion of the juice of lemons and oranges alone, though it might assist among other things. William Scoresby, jun., in his *Account of the Arctic Regions and the Northern Whale Fishery* (1820), mentioned as the diseases of scamen, scurvy, frostbite, asthma, and catarrhs, but added that the last-named were rarely followed by any dangerous consequences.

One curious feature of the vessels which undertook the African slave trade was that the surgeons they carried had to look after the slaves, not after the officers and crew. Indeed, the doctor got a bonus of one shilling for every healthy slave he landed, and one Bristol doctor, in addition to his shillings, got a present of three slaves. In the ships taking the convicts to Australia also great care was taken over ventilation and exercise. By the latter part of the eighteenth century there was constant travelling to the West Indies, a station which had a terrible reputation for sickness, but there was good health on the vessels. Prof. Nixon concluded by quoting from a schoolgirl's letter written from Jamaica in March, 1792, concerning a stormy voyage on which many were ill—"as for the mean sneaking doctor, he was such a coward that he kept in bed."

### Early Literature on Scurvy

At the same meeting Dr. GEOFFREY BOURNE gave some extracts from old literature on tissue changes in scurvy. Scurvy, he said, was known to the ancient Egyptians, as was proved by the hieroglyphs dating from about 3000 B.C. The disease beset the crusading armies of Louis IX before Cairo, and was thought to be due to the fact that the Crusaders had eaten fish which had fed on the bodies of men killed in battle. He quoted many authors, including an Austrian surgeon in 1720 who described the disease in the Imperial troops of Hungary, and made the interesting observation that the officers were less prone to the disease than the men, presumably because they had better diet. The same thing was noticed during the American Civil War, when scurvy decimated both sides. An army surgeon in that war declared that the characteristic premonitory symptom of scurvy was rheumatism.

The earliest record of the effects of scurvy on wounds was made by one Walter, a chaplain to an expedition round the world

(1740-4), who said that the whole body, more especially the legs, was subject to ulcers of the worst kind, and that the scars of wounds which had for many years been healed were forced open again by this violent distemper. Thus a man who, fifty years earlier, had been wounded at the Battle of the Boyne, and had since been well, on being attacked by scurvy found his wounds break out afresh. A number of cases of spontaneous re-fracture of bones were quoted in the eighteenth century.

In some discussion following the two papers Sir DAVID MUNRO referred to the unfortunate Indians who were released after the siege of Kut-al-amara in the last war, and who, he said, presented such starvation, with massive intramuscular haemorrhage, as he had never seen before. Dr. GWYNNE MAITLAND commented on the difference in the requirements in the various Merchant Shipping Acts right down to the present day as to the number of people on board which made it necessary for a surgeon to be carried. Dr. M. T. MORGAN (M.O.H., Port of London) said that quarantine was first established by the overseers of Venice about 1550. These people were working in the dark in the endeavour to stop epidemic diseases from getting ashore from ships, and their measures were extremely drastic. He also mentioned that it was not until 1872 that the Port of London appointed a medical officer specifically to control infectious diseases entering the port; this first officer was assisted by only one sanitary inspector, and that at a time when cholera was epidemic on the Continent. Prof. NIXON said that there was a reference to anti-scorbutics in Thomas Forrest's *Voyage from Calcutta to Mergui Archipelago* (1792), when, in addition to lemons and oranges, he also mentioned the good effect of sprouting peas and beans, which he had learned from the Malays.

### VENEREAL DISEASES IN PEPYS'S DIARY

In a recent paper on this subject<sup>1</sup> Dr. J. D. Rolleston remarks that though the medical aspects of *Pepys's Diary* have been discussed by many writers during the last fifty years, particularly by the late Sir D'Arcy Power, who dealt specially with Pepys's ocular and urinary troubles, no article has hitherto been devoted to the subject of venereal diseases in the *Diary*. The only words used in it to denote venereal disease are "clap" and "pox." The term "syphilis," though first introduced by Fracastor in the sixteenth century, for a long time did not receive general recognition, and during the seventeenth and eighteenth centuries only about a dozen writers used it. Moreover, the terms "clap" and "pox" were often used indiscriminately, the word "pox" being sometimes applied to "gonorrhoea," while the term "clap" meant "syphilis." It must also be borne in mind that "pox" was sometimes regarded not as an independent disease but as the last stage of "clap." In these circumstances, in the absence of characteristic symptoms or sequelae such as *ardor urinae* in the case of gonorrhoea, or necrosis of the nasal bones in syphilis, it is almost impossible to tell what is meant by the colloquial terms "clap" and "pox." Although chancre is probably as old as gonorrhoea, the absence in the *Diary* of a description of the local lesion makes it impossible to determine the nature of the sore, and the same applies to the other forms of venereal disease, so that venereal disease in *Pepys's Diary* must be regarded as indicating syphilis or gonorrhoea only. The high incidence of venereal disease in London, and particularly the Court at the time of the Restoration, is shown in many passages in the *Diary*, the most notable case being that of Prince Rupert, who suffered from syphilitic osteitis of the skull, for which he was trephined by James Moulins, surgeon to St. Thomas's Hospital and afterwards to Charles II and James II, and made a complete recovery. In view of the promiscuous behaviour of Charles II, the possibility of his having contracted some venereal disease naturally arises, but there is nothing in the *Diary* to support this view.

With regard to the prevalence of venereal diseases in the lower classes of society during the Restoration, it is possible that the practice of the City apprentices mentioned by Pepys of pulling down the brothels was a retaliation for infection acquired there. A remarkable epidemic of what was probably gonorrhoea was mentioned by Pepys in the Rawlinsonian collection of his miscellaneous writings. It originated in a girl, aged 14, who infected 400 soldiers, and calls to mind a similar occurrence related by Casanova. Even if, as is probable, the outbreak is somewhat exaggerated, it at least exemplifies the high infectivity of juvenile prostitutes.

Dr. Rolleston remarks that the delay in the appearance of a final and complete edition of the *Diary* which Pepys scholars must regard as one of "the minor horrors of war" will probably end soon after the termination of hostilities. It is therefore welcome news that when a new edition of the *Diary* is published 50 copies will first be privately printed with no omissions and will be presented to the leading libraries, and that the remaining copies will be published with only a few omissions.

## PROGESTIN B.D.H.

Progestin B.D.H. is the pure hormone of the corpus luteum. It thus produces a rapid progestational effect on the myometrium the motility of which is inhibited and on the endometrium the structure characteristic of the secretory phase of which is elaborated.

In the pregnant woman Progestin B.D.H. is indispensable for the maintenance of pregnancy when the natural secretion of the corpus luteum is inadequate, resulting in habitual or threatened abortion.

In the non-pregnant woman Progestin B.D.H. is effective in the relief of menorrhagia and functional uterine bleeding due to imperfect development of the secretory endometrium and in the relief of spastic dysmenorrhœa due to myometrial hypermotility.

*Details of dosage and other relevant information will be gladly supplied on request.*

### VENOUS THROMBOSIS IN THE C.N.S.

A meeting of the Section of Neurology of the Royal Society of Medicine took place on Feb. 13, with Brig HUGH CAIRNS in the chair, when the discussion was on "Venous Thrombosis in the Central Nervous System."

Dr. PURDON MARTIN, in opening, said that Maclewan in his classical work on pyogenic diseases written fifty years ago, declared that venous thrombosis was more common within the cranium than in any other part of the body. That was hardly the case to-day. Half a century ago the condition was recognized as being due to two groups of causes, the first being the so-called "maranese" group, associated with wasting diseases, and the second the infective group. The former group possibly declined first, and although the frequency of infective cases probably declined also, thrombosis in the veins and venous sinuses of the brain continued to be so generally due to infection that to many the title of the present discussion would suggest only the septic thrombosis of the lacern and cavernous sinuses. Dr. Martin limited himself principally to the non-infective cases, and he proceeded to discuss the relationship of the cerebral veins with the brain and the physical effects of cerebral venous thrombosis. These effects were very variable in degree. Haemorrhage was extensive in some instances and completely absent in others, and tissue degeneration was sometimes present, even preceding to complete softening, and in other cases was not found at all. The degree of these changes depended on the size of the vein affected and also largely on the abruptness with which the thrombosis extended and with which the circulation was impaired.

#### Clinical Features

The clinical accompaniments of these pathological changes depended first on their site; if the motor area of the brain was affected abrupt thrombosis often gave rise to severe convulsive phenomena, leaving the patient hemiplegic; or, again, the patient might become hemiplegic without any convulsion or unconsciousness, and with little or no manifestation of shock. Why convulsions occurred in some cases and not in others had not yet been determined. Convulsions seemed to him to be less frequent when there were signs of obstruction of the longitudinal sinus. If the thrombosis was at a distance from the motor area the symptoms often appeared without convulsive phenomena; for example, with lesions in the pre-frontal area convulsions were not common, though some degree of weakness might develop, and when the lesions were posterior to the central gyri convulsions in his experience did not occur.

As for other clinical features, speech was rarely involved, though he had seen one instance of complete right hemiplegia with total aphasia. On two occasions he had seen word-blindness and on two others visual disorientation as part of the symptomatology. The immediate prognosis in a given case was difficult to assess. In the convulsive stage the symptoms were always very alarming, but in his experience fatalities were few. Once the convulsive stage was over, recovery from the hemiplegia might be rapid and more or less complete within a fortnight. In many cases, however, recovery was imperfect, and in fact the most complete and most spastic hemiplegia might be left as a permanent disability. In general, prognosis for recovery of function was much better than in cases of arterial thrombosis, and in a large proportion of cases was good.

#### Cases associated with Childbirth

Dr. Purdon Martin added that he had been particularly interested in the group of cases in which thrombosis in cranial sinuses or cerebral veins occurred in association with childbirth. In most instances, but not all, the manifestations developed during the puerperium and generally between 4 and 21 days after confinement. He had encountered two cases and a probable third in which the symptoms developed during pregnancy, and in each case the patient had a stillborn child, which raised in his mind the possibility that thrombosis might have occurred first in the placenta. Why should thrombosis associated with childbirth occur within the cranium? Here he drew attention to the connecting channels between the pelvic veins at one extremity and the cranial sinuses at the other. In the vertebral canal, and winding in and out between the laminae, was a plexus of veins of considerable size. By injecting these veins with radio-opaque material it had been shown that the passage was free right up from the veins on the floor of the pelvis to the base of the cranium, and was continued into the cranium by a number of smaller veins. If anything did pass up it seemed most likely that it was a small piece of clot, because it was known that such pieces of clot found their way into the iliac veins and so caused pulmonary emboli; pieces of meconium and other elements derived from the amniotic fluid were also said to find their way into the circulation.

Two special factors might be responsible for the occasional direction of material into the vertebral veins—namely, pressure on the inferior vena cava or on the iliac veins, most likely to occur before delivery, and the great enlargement of the pelvic and neighbouring vessels during pregnancy. If any element did pass up, it left, as a rule, no trace of its passage; but one of his patients suffered from a spinal lesion as well as a cerebral one, and in another instance a patient developed complete paraplegia two days after septic abortion, and post mortem there was an abscess involving the tibia at the ninth dorsal vertebra, and no abscess anywhere else in the body.

Air Vice-Marshal C. P. SYMONDS mentioned the frequent occurrence of sudden substernal pain and dyspnoea as a premonitory sign of the thrombosis. He recalled only one case of cerebral thrombophlebitis following dental extraction. There were still several problems left unsolved in connexion with the mechanism of this very curious and not infrequent clinical picture of increased intracranial pressure with increased cerebrospinal fluid pressure and papilloedema. What was wanted was some more direct evidence obtainable by x rays, using the injection of a contrast medium into the superior longitudinal sinus.

Miss DIANA BEST recounted some experimental work which went to show that in the cat and dog the greater part of the superior longitudinal sinus could be obliterated without any inconvenience to the animal. Evidently the collateral circulation was so good that it at once compensated for such disturbance. Dr. DOROTHY RUSSELL described the case of a boy with symptoms of otitic hydrocephalus who was treated in hospital for that condition for some time and improved but died of a concurrent disease (tuberculosis). She was almost sure that the degree of hydrocephalus demonstrated post mortem was less than would have been shown some weeks before death. She suggested that the ventricles changed their size in different phases of the condition.

Dr. RUSSELL BRAIN said that he had collected at Moorfields a small group of cases in which ophthalmoplegia occurred within a few days of dental extraction. In all the cases, he believed, the extraction was in the upper jaw, and the ophthalmoplegia occurred on the same side. He also mentioned a group of cases not so far described in which a cortical thrombophlebitis complicated thrombophlebitis migrans originating in the lower extremities. Mr. D. W. C. NORTHFIELD asked how the diagnosis was made between cortical thrombophlebitis and possible complicating infective abscess.

Dr. PURDON MARTIN replied that if there were no convulsive phenomena at the beginning it might be very difficult to make the differential diagnosis. In the case of abscess the symptoms were likely to extend gradually; in venous thrombosis there was usually spasmodic extension. Air Vice-Marshal SYMONDS said that the right way to look at the question was to regard thrombophlebitis as one of the means by which abscess developed, and when a diagnosis of cerebral thrombophlebitis was made, the possibility of abscess should be suspected.

### ACUTE CATARRHAL OTITIS MEDIA

In the Section of Otolaryngology of the Royal Society of Medicine on Feb. 4 Major GORDON D. HOOPLE, U.S.A.M.C., presented some clinical observations on acute catarrhal otitis media.

Major Hample said that his remarks were limited to otitis media complicated by non-purulent fluid in the middle ear. No term was adequately descriptive of this condition, to which he gave the title "acute secretory otitis media." In 748 patients in the United States seen in his clinic, 619 had infection of the nose or throat just before the onset of the ear symptoms; over 100 showed no evidence whatever of infection either before or during the course of the otitis. There was a marked deviation of the nasal septum on the affected side in 107 cases. He had also seen in a short Army experience 32 cases—12 right-sided, 12 left-sided, and 8 bilateral—almost all of which had followed operations or infections.

Any condition which created swelling in the region of the Eustachian tube could be a causal factor. The fact that the process involved the entire middle ear and not the tympanic cavity alone had not been sufficiently stressed. The history, if typical, would lead one towards the diagnosis. The condition usually followed deafness in one ear or both consequent upon a cold. Examination in the inflammatory stage would show dilatation of blood vessels of the atrium. Bubbles of air in the fluid gave a characteristic appearance. The condition was more difficult to diagnose when the tympanic cavity was completely filled with serum, and the only identifying feature was the over-all amber colour of the drum. Still more difficult to diagnose was the ear filled with fluid, when the drum was so thickened as to show no change in colour, and the loss of hearing was ascribed to the thickened drum.

The 748 patients mentioned had been seen over a period of some years, during which the routine of management had altered, but in latter years treatment had been fairly consistent. Patients were classified in two groups: those in whom the condition was of infective, and those in whom it was of non-infective, origin. To eliminate the infection was the first goal of treatment in patients with acute inflammation, but it might well be that many cases in the first group were classified as due to infection when in fact the infection was not causal but collateral. Nothing was done to these ears until the infection had cleared up. Following this, catheterization with gentle inflation was carried out. If the collection of serum persisted after one or two catheterizations, paracentesis of the membrana tympani was done and the ear was inflated to allow of the escape of some of the fluid. Paracentesis was repeated at intervals of a few days. It was done without anaesthesia, and whilst this caused some discomfort, it was minimal when done in an uninfamed drum.

The nose and nasopharynx of patients in the non-infective group were first swabbed for evidence of infection, and if this was negative other possible causes were looked for—such as allergy and endocrine disorders. In the so-called subacute or protracted cases such additional therapy as seemed indicated was instituted.

In the course of a short discussion Col. NORTON CANFIELD, U.S.A.M.C., suggested that low-grade bacterial infection probably played some part in this condition. Mr. LESLIE POWELL was surprised to hear that allergy was supposed to be an aetiological factor, because his experience was that in spite of the very obstructed nose in hay-fever and other conditions there was no effect on the ear. He believed the catheter was used much too often and for too long periods.

#### Radiotherapy of Malignant Disease of Middle Ear

At the same meeting Prof. B. W. WINDEYER gave a paper on radiotherapy of malignant disease of the middle ear, reporting eight cases of this relatively rare condition which had been treated at the Middlesex Hospital since 1935. Of these eight cases seven were intrinsic growths; it was doubtful whether the eighth was intrinsic or a recurrence of growth elsewhere. Five of the growths were squamous-celled carcinoma; the others were transitional-celled carcinoma, angio-epithelioma of moderate malignancy, and one was undifferentiated. The treatment given was similar to the treatment of malignant growth of the accessory nasal sinuses—namely, a course of radiotherapy carried to a high dose by means of teleradium or x rays, followed, after the reaction had subsided, by radical mastoidectomy to remove any remaining tumour as widely as possible, to provide exposure for subsequent treatment either by radium implantation or localized x-ray treatment, and to furnish a cavity for subsequent inspection. Necrosis of bone or cartilage was obviously the complication most to be feared, and there had been necrosis of cartilage in two of his cases in which the dosage received was heavy. In later cases, however, care was taken to prevent overlapping and to direct beam more accurately, and among these there had been no necrosis, although an equally heavy dose had been given. Some of the cases were very recent, and any conclusion must be drawn with great care, but so far there had been no evidence of new growth among the cases kept under observation.

Mr. C. P. WILSON, who was concerned with the surgical treatment of these cases, said that the results obtained were sufficiently encouraging to make one feel that the lines on which treatment had been pursued were reasonable and offered some chance of giving permanently good results.

O. Mickelsen and A. Keys (*J. biol. Chem.*, 1943, 149, 479) have analysed sweat collected from different parts of the body of normal young men at rest and doing moderate work. It was found that the composition of sweat varied according to the part of the body from which it was collected. Sweat from the hand, for example, is more concentrated in chloride than the total body sweat formed at the same time. Lactate, urea, and ammonia were more concentrated in the sweat than in the blood. Ascorbic acid, thiamine, riboflavin, and nicotinic acid are lost in sweat, but the authors conclude that, even with profuse sweat, losses of the first three are insignificant from the nutritional standpoint. But they observe that "the sweat loss of nicotinic acid under these conditions could be significant. . . ."

## Correspondence

### Infant Mortality in Scotland

SIR,—Under ordinary circumstances the letter by Major S. F. Markham, M.P., on the Scottish infant mortality report (Feb. 5, p. 193) would not call for any reply. But as the report is to be discussed in the House of Commons and the letter has been reproduced in parts in the lay press, the general public and even Members of Parliament, who are not always well informed on medical matters, seeing newspaper quotations from the leading medical journal, may think that these represent the views of a section of the profession.

Mr. Markham's first criticism is that the committee did not consider fully the effects of evacuation and other temporary factors arising in the present emergency. The committee was not appointed for this purpose. It was appointed because for many years before the war the infant mortality rate in Scotland was between 30 and 40% higher than in England. It has remained at that higher level during the war. The Secretary of State for Scotland, who is considering measures for a better post-war Scotland, therefore appointed a purely Scottish committee to consider the more permanent factors causing the relatively high infant mortality rate in Scotland. Medical men will, of course, agree that it would be premature for a committee appointed in 1941 to attempt to evaluate the relative importance of the many temporary factors arising during the war.

The next criticism is that the mortality rate quoted for South Africa applies only to the white population and not to South Africa generally. The reason, of course, is that there are no exact data on the infant mortality rate of natives in Africa still living under native conditions, and even if such data were available they would not throw any light upon the high infant mortality rate in Scotland.

Then the committee is blamed for not obtaining statistics on the percentage of the insured population unemployed in English cities. Mr. Markham's impression is that such information is available in the Ministry of Labour statistics. The committee tried to get this information, but was informed by the Ministry that it was not available. He states that the bibliography shows gaps and that the research of three workers he names is not referred to. The report is pretty fully documented, but, as every medical man knows, there are thousands of papers on the subject, and a complete bibliography quoting every one of them would not have added to the value of a report to a Minister of State who is not interested so much in fundamental research as in the practical measures that should be taken to apply well-established knowledge.

The main burden of Mr. Markham's criticism, however, is that sufficient attention was not paid to the effect of climate on health. He himself has written a book on *Climate and National Energy*. He gives some figures showing that at the moment of birth an infant passes from 99° F. to 50° F. or even 40° F., and states that extensive research carried out at a hospital in the United States showed that at temperatures of 77° F. the mortality of premature infants was reduced from 29 to 0.7%. If it is a fact that the mortality of all premature infants could be reduced from 29 to 0.7% by simply keeping them warm and regulating the humidity, then the medical profession should be regarded as hopelessly incompetent. As a matter of fact the figures quoted only apply to a small selected group of infants, and, as every medical man knows, only a small proportion of premature infants can be saved by the methods referred to. These methods are being carried out as efficiently in Scotland as in America.

Mr. Markham states that the average Scottish household of 3 to 5 persons spends 13% less on coal, gas, or electricity than in England. The obvious explanation is that, in proportion to the population, there were before the war six times as many people in Scotland living in unhygienic and overcrowded houses as in England. The number of rooms occupied by the average Scottish household of 3 to 5 persons is, therefore, fewer than in England. The overcrowding is an obvious cause of high infant mortality, but the fact that people in small houses use less coal and light than people in larger houses has no bearing on the question.

Mr. Markham pursues this subject of climate at some length. The committee considered the effect of climate and pointed out that mortality is much higher in winter than in summer, but came to the conclusion that the effect of climate is more than offset by other influences. Mr. Markham considers this "an incredible statement" in view of the fact that Scotland is, on the average, 5° colder than Southern England. If climate were the main factor one would expect the Shetland Islands, the most northerly part of Scotland to have a higher infant mortality rate than towns on the Firth of Clyde. In the pre-war quinquennium the rate in Shetland was 39 and in Clydebank 83. Iceland should have a high rate and Portugal a low rate. The rate in Iceland was 48 and in Portugal 147. In the

quinquennium 1896-1900 the rate in Scotland was 20% lower than in England and 16% lower than in Holland. In the period 1934-8 the rate in Scotland was 35% higher than in England and almost 100% higher than in Holland. There is no evidence of any drastic change in climate which would cause these changes in the relative infant mortality rates.

The last point made by Mr. Markham is one in which he refers to "Wooltonized diets." In this connection he says that, although the diets have been "Wooltonized" and there is little unemployment or poverty in Scotland, the infant mortality rates are still excessively high, while the English figures are now the "lowest on record, in spite of housing difficulties of an unprecedented degree." This argument is not very clear unless, indeed, it is that bad housing and poverty are not important factors in a high infant mortality rate, and that improvement of the diet by the Government food policy, which makes special provision for mothers and infants, has had a marked effect in England but none in Scotland. As a matter of fact, the changes in infant mortality in Scotland during the war run roughly parallel with those in England. In both cases the rates rose in the beginning of the war, and in the last two years have fallen by about the same proportion. The provisional rate in Scotland for 1943 is 65 per 1,000 compared with 77 in the pre-war quinquennium.

Such are the reasons given for the statement that the committee "skipped its job" and "regarding environmental conditions generally," made "not a helpful suggestion in the report." The main recommendations in the report made to the Secretary of State for Scotland are briefly as follows:

- (1) Every effort should be made to improve housing without waiting for formal town planning.
- (2) The means taken by the Government to improve the diet of mothers and infants should be extended as more food becomes available.
- (3) Child welfare services should be extended and improved.
- (4) Ante-natal clinics should be an essential part of the obstetric service and staffed by obstetricians.
- (5) The number of beds available in maternity hospitals should be increased; the nurseries should be improved with special cubicles for premature infants.
- (6) Medical and general education should be improved.

The committee was unanimous in making these recommendations, and there is little doubt that medical men, however their views may differ with regard to the relative importance of the factors causing the high infant death rate in Scotland, would agree that these measures would reduce the rate and that they are the kind of measures which any committee of experts would have submitted for the consideration of the Secretary of State. Unfortunately there are too few members of the medical profession in the House of Commons. The debate is liable to be confused by speeches by politicians who are not well informed on the subject. It is to be hoped that all the medical members will give full support to the measures proposed, and thus assist their colleagues in Scotland to eliminate the main causes of the high infant mortality rate. The medical profession can do little more than it has done under the specially adverse conditions in Scotland. The remedy lies in Government action on a national scale.—I am, etc.,

DUGALD BAIRD,

The University, Aberdeen.

Chairman of Drafting Subcommittee.

SIR,—There is one factor in common to all those countries which have reduced their infant mortality to an enviable low level—namely, the first and most marked reduction has always been due to a fall in the death rate from preventable gastro-intestinal and respiratory infections. In Scotland infant mortality from these causes is still excessively high, and has shown no reduction for a quarter of a century. It would seem, therefore, that the first attempt to reduce Scottish infant mortality should be a direct attack on these two groups of infections, both of which are closely correlated with poverty.

The infant death rate from respiratory diseases in Scotland is higher than in some other countries with an equally bad climate. Low fuel consumption may be a factor, as Major Markham, M.P., in his letter suggested, but only an indirect one, in that it limits the household to one fire no matter how large the family. Instead of suffering from exposure to a low temperature, the infant is subjected to an intense barrage of droplet infection in an overheated, overcrowded room at a time of year when respiratory diseases are most prevalent.

Major Markham states that from 1940 to 1943 there was singularly little unemployment or poverty in Scotland, but the infant death rates remained high. This is not surprising, as the

temporary abolition of poverty was largely theoretical. Mere increase of money, with its reduced purchasing power, both in quality and quantity, has not enabled the poor to improve or relinquish their environment in these years of war. The whole problem of reducing infant deaths from respiratory infections is that of the factual abolition of the environment of poverty and of the habits engendered therein. It not only involves rehousing but also a simultaneous raising of the standard of living. A family, rehoused from a slum, will continue to live in a slum environment as long as economic necessity forces it to economize in fuel or to sublet rooms.

The high infant death rate from gastro-intestinal diseases in Scotland is associated with the combination of poverty and incorrect artificial feeding. A whole generation of health visitors has failed to reduce these deaths. In several years' experience of maternity and child welfare I have noticed that, below a certain economic level, a mother does not benefit from good advice. She has not the necessary apparatus for the correct preparation of artificial feeds, but she does not lack the actual ingredients for correct feeding, as these are provided by the Government, free if need be, for every infant in the country. I wish to make a suggestion which has not, so far as I know, been tried in this country. I suggest that the Government should set up depots for infant feeding in all areas where there is a high infant death rate from gastro-intestinal diseases, and that these depots should provide daily to all artificially fed infants in these areas a 24-hour supply of feeds, correctly prepared for the child's age and individual requirements, sterilized, and bottled into separate feeds, ready for use (except for rewarming). I know of no other rapid way to ensure the infant a reasonable chance of a correct, almost germ-proof and almost fool-proof, food supply. There is little chance of abuse, for these feeds could not be a saleable commodity, as were tins of dried and liquid milk obtained free at clinics. I saw this plan in operation when visiting infant welfare clinics in Moscow in 1934. Each mother brought her crate of "empties" to be exchanged for a full one. The scheme could be worked either through an extension of existing infant welfare clinics or by a paediatric team attached to a hospital. It should be accompanied by an intensive and unremitting campaign for breast-feeding. Incidentally, by rendering it difficult for a mother to discontinue breast-feeding prematurely on her own initiative, it would lessen the number of bottle-fed babies.

The plan would require organization and expenditure. This was also true of diphtheria immunization and of A.R.P. It could be a temporary measure during this stage of social transition, pending rehousing and other means of raising the standard of living. It might effect an immediate improvement in the infant death rates from gastro-intestinal diseases, which at present account for roughly one-tenth of Scottish infant mortality.—I am, etc.,

Colhai, Aberdeen.

MARGARET S. M. MCGREGOR.

### "Immersion Foot" and Cold Therapy

SIR,—In their article on the aetiology of "immersion foot" (Feb. 12, p. 218) it appeared to me that Goldstone and Corbett implied that frost-bite and trench foot were probably synonymous terms. This, however, is far from the truth. As long ago as 1915, while investigating trench foot in the last war, I showed that there was an essential difference between this and true frost-bite. There is a critical temperature in the region of  $-5^{\circ}$  C. above which individual tissues will survive for prolonged periods, while below this temperature immediate death occurs owing to protoplasmic disruption. This critical temperature is beautifully demonstrated when tissues growing *in vitro* are the subject of experiment. That the temperature is so far below zero is due to the exhibition of the phenomenon of supercooling in protoplasmic tissues.

It has, of course, never been suggested that immersion foot bore any relationship to true frost-bite, but that it closely resembles trench foot, both in the circumstances of its origin and its clinical course, cannot be denied. The gangrene, when it occurs in these cases, is a secondary event due to vascular changes, and in the experimental animal can actually be prevented by tying the main artery to the limb, so limiting the exudate, or alternatively by the use of local vasoconstrictors

(not vasodilators as the authors of this article suggest). Indeed one of the most certain ways of precipitating gangrene in the chilled limb is to bring about vasodilatation by heat or other means. A summary of the experimental work which led to these conclusions nearly thirty years ago will be found in chapter 23 of the third edition of *The Foot* (Lake) or in *The Surgery of Modern Warfare* (Bailey).

Incidentally the article on dry cold therapy by Bigelow and Lanyon in the same issue (p. 215) raises some points of a similar nature. At long last the virtue of keeping parts temporarily deprived of their blood supply (whether this be due to blocking of the larger arteries or local ischaemia due to the pressure of exudates) in cold storage is becoming recognized, and the specific indications for refrigeration are being worked out.

To quote from the chapter on frost-bite in *The Foot*: "The main indication for the therapeutic use of the method (refrigeration) is in those cases where a collateral circulation may be confidently expected to develop within a reasonable time if the limb in the meanwhile can be prevented from undergoing gangrene. The results are less notable in the more chronic cases—i.e., thrombo-angiitis, etc.—but even in the senile cases the relief of pain will often enable one to postpone the inevitable amputation to the most propitious moment."

"We may sum up the position, therefore, by stating that a cold (i.e., in the region of 0° C.) limb requires no blood supply, since all its tissues are in a state of suspended animation, and as a corollary, a limb depleted of its blood supply should be kept cold, otherwise its tissues cannot retain their vitality."—I am, etc.,

NORMAN C. LAKE.

### Recognition of Anaesthetic Gases

SIR.—The Council of the Medical Defence Union is at present actively engaged with the Association of Anaesthetists in a review of certain difficulties experienced by anaesthetists with respect to the recognition of the actual gas or gases delivered to and from anaesthetic apparatus. It is hoped in the near future that it will prove practicable to submit to your readers a full report on the measures proposed by the above bodies for adoption by those concerned to obviate errors of wrongful coupling or of misidentification of the gas or gases in use.

For the present all anaesthetists of whatever experience and qualification are urged to satisfy themselves personally of the actual gas about to be administered to a patient and not to rely upon the assurances of other parties. The factor of personal responsibility should never be absent from the mind of an anaesthetist, with the result that before commencing the administration of any gas or mixture of gases he should check his apparatus and cylinders completely to satisfy himself beyond reasonable doubt on the character of the gaseous anaesthetic he proposes to administer to a patient.—I am, etc.,

ROBERT FORBES,

Bedford Square London, W.C.1 Secretary, Medical Defence Union.

### Intravenous Anaesthesia

SIR.—Mr. J. F. O'Connor (Feb. 5, p. 199) has raised several points in connexion with our article on intravenous anaesthesia (Dec. 25, p. 813) which we would like to answer.

1. *Use of Table.*—In practice we stand our saline container on the table of the Boyle's apparatus (the very stable hospital pattern) from which we administer the supplementary nitrous oxide and oxygen. If the site of operation necessitates the use of a leg vein for the intravenous drip, a separate table will not be in the surgeon's way. The anaesthetist as well as the surgeon must have the right of access to some part of the patient.

2. *Use of Hand Bulb.*—We agree that this requires more frequent attention than the method of choice—i.e., using the oxygen cylinder to provide positive pressure—nevertheless, if the hand bulb is used, a screw clip or pair of ovum forceps applied to the tube when the pressure has been raised in the bottle will prevent any leak, and the hand bulb need only be used at long intervals when the drip is seen to slow up. So long as any pressure remains in the bottle, saline must flow into the vein, and there is no question of blood running back into the needle and clotting. A gravity drip-stand must be tall to provide the necessary pressure and will be, therefore, either top-heavy or have a wide base to get in the surgeon's way.

3. *Fixing Needle.*—The three pieces of strapping as described in our article have always proved adequate. The extra strapping suggested by Mr. O'Connor would give greater security.

4. *Pressure Tubing.*—We agree, any good rubber tubing will suffice. Under wartime conditions this is in short supply, and we mentioned pressure tubing to prevent the leakage of saline from the puncture sites.

5. *Premedication.*—We normally use as a maximum omopon 1/3 gr. and seopolamine 1/150 gr. given 1½ to 1½ hours before operation; this time allows its maximum hypnotic effect to be attained and its most marked respiratory depression to have passed. We believe that the large doses of morphine up to 1/2 gr. as suggested by Mr. O'Connor have too marked an effect on respiration especially when the anaesthetic drug to be employed is itself depressant.

6. *Vomiting.*—The use of analeptics to hasten recovery is known to increase the incidence of post-operative vomiting. We agree with Mr. O'Connor that this sequel is often attributable to the morphine and would be a further reason for limiting the pre-operative dose of this drug and restricting its indiscriminate use post-operatively. We have noticed that in many cases there is a long period between return to consciousness and the onset of vomiting, and this can often only be explained as a result of post-operative opiates.

7. *Dosage.*—We would like to state categorically that there is no such thing as a maximum and minimum "dose" of pentothal, any more than there is a "dose" of chloroform or ether. The amount given must be regulated by the susceptibility or resistance of the individual patient, the length and depth of anaesthesia required by the surgeon, and this can only be determined as the operation proceeds. Excessive quantities of pentothal or any other anaesthetic will delay recovery, and to our minds this prolongation of respiratory and circulatory depression is a potent factor in the aetiology of post-operative complications. As was stressed in our paper, it is considered most important that for any but the shortest operations intravenous anaesthesia should be supplemented by nitrous oxide and oxygen. For operations not requiring much relaxation—e.g., skin grafting, suture of multiple lacerations, simple herniotomy, etc.—an induction dose of 1/4 to 1/2 g. of pentothal supplemented with nitrous oxide and oxygen will maintain anaesthesia for 1/2 to 3/4 of an hour. For longer operations or those requiring greater relaxation the same method is used, but smaller repeat doses of pentothal, 0.05 to 0.15 g., are given as required. Even for the longest operation requiring the deepest anaesthesia we have rarely if ever had to use more than 2 g.—i.e., 40 c.cm. of 5% pentothal. We consider it wiser to obtain such profound and prolonged relaxation by a combination of a regional nerve block or spinal analgesia and a light general anaesthetic (such as nitrous oxide and oxygen following a pentothal induction). For the majority of such cases as hysterectomy, prostatectomy, and appendicectomy, etc., 1 g. (20 c.cm.) of pentothal plus nitrous oxide and oxygen has been found to be quite sufficient.

In conclusion we should like to thank Mr. O'Connor for the interesting points he has raised in his letter and to sympathize with him in his double responsibility of operating while supervising the anaesthetic. We feel that this difficulty is closely allied to the whole problem of undergraduate and postgraduate teaching of anaesthetics, the solution of which is not assisted by the unavoidable production during wartime of many semi-specialist anaesthetists.—We are, etc.,

F. W. ROBERTS.  
B. A. SELICK.

Middlesex Hospital, W.1.

### Treatment of Chronic Nephritis by Serum Transfusion

SIR.—I find Dr. J. H. Hannan's letter on this subject (Feb. 12, p. 232) confusing. He states that serum transfusion in shock and haemorrhage has been well established; inferentially its use should follow in the treatment of "chronic nephritis or nephrosis." "Nephrosis" is the term he prefers to use in cases of chronic nephritis with presumably oedema. Where is the connexion?

In shock and haemorrhage serum may be used to increase the circulating blood volume; in the nephrotic syndrome there is no significant reduction in the C.B.V. Protein solutions are used here to maintain the blood reservoir, and, especially when given in "hypertonic" concentrations, to promote oedema resorption and diuresis; moreover, serum may be dangerous in the treatment of haemorrhage by acting as a blood diluent.

I deplore the use of the term "nephrosis" for cases of chronic nephritis with proteinuria and oedema, and do not agree that in these cases we restrict the protein intake, nor do I see why "protein obtained from and at the expense of the body cells" increases oedema. The "nephrotic syndrome"

occurring in nephritis mimics "nephrosis" is not entity and a rare disease, whose study has thrown little light on the mechanisms of renal oedema. In this condition there is massive proteinuria, widespread oedema, and severe hypoproteinaemia, and good renal function without azotaemia. It is precisely in these cases that a liberal policy is followed in an attempt to maintain tissue and blood protein levels to compensate for the urinary loss. Azotaemia, if it is to be regarded as contraindicating a liberal policy, is not found often, and when present is usually due to severe oliguria with pre-renal deviation of water balance, which is corrected by diuresis. A high protein intake, or even such a diuresis, particularly in the nephrotic syndrome, has been maintained previously on an entirely sound rationale. Furthermore salt and water balance and the administration of urea should secure a sufficient intake to correct these minimal azotaemias.

One of the most important factors in the pathogenesis of hypoproteinaemia. In a nephrotic patient the loss of blood protein at the expense of the tissue protein, with the tendency to oedema, but there will be a tendency to the degree of tissue destruction. In dehydrated patients with uraemia such a process occurs, the oedema is not, but polyuria and dehydration are present and there is an accumulation of those toxic products of abnormal protein catabolism which accompanies and perhaps causes the toxic state that we call "uraemia."—I am, etc.,

### Preventing Necrosis of the Tabula Externa in Head Wounds

SIR,—In your issue of Feb. 5 (p. 185) Dr. D. Engel calls attention to a very useful method designed to prevent necrosis of the tabula externa of the skull denuded of periosteum. The plan is certainly not new, but I regret that I cannot state from whom I first learned it as long ago as 1905. Since that time I have used it on several occasions and have found it to be most helpful. I am sure it will assist the separation of bone which is beyond hope of survival, but even when the surface is white, dry, and apparently devoid of life granulations soon spring up through the holes made into the diploe and spread over a considerable surface in a most remarkable way. I have used the method when quite large areas of cranium have been exposed, and it is interesting to observe how the advancing scalp edges will grow over the granulations, which soon cover the affected area, but, of course, without the hair.

I am personally much indebted to Dr. Engel for the very useful diagram which accompanies his short note.—I am, etc.,

G. GREY TURNER,

Professor of Surgery,

British Postgraduate Medical School

-London, W.6.

### Sciatica

SIR,—The fog about this subject of which Sir Arthur Hurst writes in his letter (Feb. 5, p. 194) will not, I am afraid, be dispelled by his words either in that letter or in his original "essay in debunking." It would be a pity if this correspondence ended without the subject being made as clear as possible in the present state of our knowledge. In his evident anxiety to disparage the orthopaedic surgeons and to knock their heads together, Sir Arthur has, as Mr. Harry Platt said, done scant justice to those who, both in Britain and the U.S.A. during the last twenty-odd years, have made great and successful efforts to solve the problems of spinal pathology, and so to elucidate the symptoms, such as sciatic pain, which can arise from its various forms.

Sir Arthur has misinterpreted the remarks made by myself and others in a number of instances, but it is a relief to find that he does allow that "almost all cases of sciatic pain have a physical basis at the onset," though unfortunately he goes on to say that this "generally disappears rapidly" with the panacea of rest and persuasion. One would have expected that a great pioneer in this country of thorough investigation of disease would have advised determination and treatment of the physical basis of sciatic pain as the first step. Explanation, persuasion, and re-education are certainly most important, and are appreciated by orthopaedic surgeons as much as by anyone; but their use without determination and treatment of

the physical state would not be "simple psychotherapy" but simple humbug. The difference between Sir Arthur Hurst's attitude and that of orthopaedic surgeons is that he apparently thinks that the physical state may be disregarded while they consider it primarily important.

It would perhaps help understanding of the incidence of the different causes of sciatic pain if we divided cases into those over and under the age of roughly 40. Under 40 is the period during which posterior disk rupture may occur, and its incidence among cases of sciatic pain during this period may well be as high as the figure of 20% which Sir Arthur mentions. Indeed Jackson (*Journal*, Dec. 18, 1943, p. 776) states that 18 out of 100 cases treated at an E.M.S. hospital during 1942, mostly from the Services and therefore presumably between the ages of 20 and 40, were proved by operation to have posterior disk rupture. But the figure of 2% which I gave is the probable incidence for all cases of sciatic pain if all ages are considered, and corresponds with the percentage given in the large series of the Mayo Clinic. Thus it seems that confusion on this point is due to failure to distinguish between young adult and older cases. Again, in middle-aged and elderly patients there is no doubt that the spinal arthritis of which Mr. Blundell Bankart writes is by far the most common cause of sciatic pain, and since such pain is more often experienced in middle and later life, spinal arthritis in its various forms is, as Mr. Bankart says, in general the commonest cause of sciatic pain.

The points I have tried to make in this discussion are that: (1) in almost all cases of sciatic pain there is a determinable physical basis; (2) both pure hysteria and malingering are rare (though there is often an associated psychological factor); (3) the physical basis is either (a) a state of the fibrous tissue of the ligaments or fasciae in the lumbo-sacral or gluteal regions due to fibrositis, trauma, degeneration, or strain associated with postural disorder, malformation, arthritis, or other deforming disease, or (b) a source of irritation of the roots of the lumbo-sacral plexus; (4) in most cases the pain in the limb is purely referred: only in perineuritis or in pressure on the nerve roots as by a posterior disk rupture are there accompanying neurological signs; (5) disk rupture is an important though relatively uncommon cause of pain if all cases at all ages are considered; it occurs practically only in adults between the ages of roughly 20 and 40; (6) there is a danger of unnecessary operation if cases of persistent sciatic pain are thought to be only neurosurgical; (7) every case should be thoroughly examined to determine the physical as well as the psychological state before treatment, as only in that way can treatment be rational.—I am, etc.,

Bournemouth.

N. ROSS SMITH.

SIR,—Much ink has been spilt about sciatic pain and disk protrusion in recent issues of the *Journal*, and I have hesitated long before adding my own quota. However, Dr. Coldrey's letter (Feb. 12, p. 231) has prompted me to write, and I hope that my contribution to this correspondence may be of value in view of the personal experience involved.

I have suffered from pain referred along the distribution of the sciatic nerve, combined with an unenviable collection of extremely tender nodules in the lumbar region. I know from bitter experience what this pain is like and how it completely limits one's activity. I know, too, the disappointment felt when local measures, including rest, heat, massage, exercise, local novocain infiltration, and epidural injections failed to influence the condition. I have observed these things in myself, and also the ultimate result of correct treatment, and, being a doctor, perhaps my observations may not be without interest.

Fortunately (perhaps Dr. Coldrey would disagree with my adverb) I was seen by a neurosurgeon, who, after full investigation, diagnosed a herniated nucleus pulposus and subsequently removed it. Now, from the first conscious moment after recovery from the anaesthetic, the dreadful referred pain had gone. To be sure there was pain at the wound site for a few days, but the characteristic pain that I had suffered for months had gone, and has never recurred. Of that I am quite sure. There may be some who would say that any form of treatment would have the same result—a psychological one—but I had other forms of treatment, and I did not light-heartedly demand

operation out of impatience or for any other reason. The interesting feature is that the nodules in the lumbar region, though fewer and smaller, are still present, but there is no local or referred pain on handling them even roughly. This is 3½ months since operation.

I believe that these results are secondarily produced in the lumbar muscles and fascia along the distribution of the posterior primary rami of the lumbar nerves by reason of the irritation of the protruded disk at the level involved. I refer, of course, to irritation of the nerves within the vertebral canal. Furthermore, my experience suggests to me that such nodules are only painful so long as some irritative process is affecting the nerve roots. Many types of irritation, of which disk protrusion is only one, may act in this way in so-called fibrositis cases. I am now back to full duty with no disability at all and no trace of my former pain. I am able to execute movements that were quite impossible before operation.

Let someone who has had sciatic pain (I shrink from using the word "sciatica") decide whether it is impatience that compels the sufferer to seek more thorough investigation and more radical treatment than some of your contributors would offer. As for the suggestion that a functional element is present I heartily agree that this is so, but I suggest that anyone who has been incapacitated by this terrible pain and knows the agony of sneezing, knows, too, how it feels to be awakened at night by the pain caused by involuntarily turning in bed, will develop an anxiety state about his condition, especially after the failure of local measures. Let me assure anyone interested in this condition of disk protrusion that the pain is really dreadful and its continuance is demoralizing.

In my convalescence I was lucky enough to see operations performed for the same condition, and I can assure anyone that the protrusion is very real, and that the affected nerve is stretched and swollen over the protrusion. I am awaiting with interest an authoritative survey of such cases by the neuro-surgical team concerned, and the fact that such a publication is still delayed should chasten all of us who leap into print and controversy about this matter of disk protrusion without knowledge of all the facts and experience of many proven cases. For my own part, I know of the benefit of operation in my own case and in the case of at least one other doctor with whom I shared a room in hospital. I have not made any mention of the investigations undertaken in my own case or of the post-operative treatment, as I believe that these matters rightly belong to the detailed survey of cases which I hope to read soon—I am, etc.,

Aberdeen

MALCOLM R. MILNE.

SIR, -Much of the confusion which surrounds discussions on sciatica arises from the inaccurate use of terms. Sciatica is not a disease, and it is not a symptom; it is a syndrome. In other words, the term "sciatica" denotes a group of symptoms and physical signs which indicate an affection of the roots or trunk of the sciatic nerve, from whatever cause arising. Thus, pressure by a malignant growth, diabetes, trauma, exposure, retropulsion of the nucleus pulposus, and perineuritis may all cause sciatica, for they may all affect the roots or trunk of the sciatic nerve. The term "primary sciatica" might well be employed for the benign condition of which the assumed pathology is a perineuritis or interstitial neuritis, and "secondary sciatica" for all other affections of the trunk of the nerve or its roots. Unfortunately the term "sciatica" is often used as a kind of topographical designation to indicate pain of any sort between the crest of the ilium and the ankle. Thus under the head of "sciatica" Prof. Platt and Dr. Cyriax include long catalogues of morbid conditions which bear only the most remote resemblance to true sciatica and which may be distinguished from it by a simple clinical examination. When the presence of the sciatic syndrome has been established, the task then arises of determining its nature, and here the differential diagnosis may be difficult. This, however, is a subject outside the scope of a letter, but it may here be said that retropulsion of the nucleus pulposus is more frequent than is usually supposed, and that the majority of such cases ultimately recover without operation, which should be reserved for the more protracted and severe examples.

I entirely agree with Sir Arthur Hurst that sciatic symptoms are often prolonged by the injudicious continuation of treat-

ment (post-sciatic hysteria). At an appropriate stage all treatment should be stopped, the search for nodules should be rigorously forbidden, the patient should be assured that the twinges and paraesthesia will pass away in time, and he should be encouraged to return to his affairs.—I am, etc.,

Edgar Allen Institute, Sheffield.

R. G. ABERCOMBIE.

### Umbilical Hernia in Children

SIR,—May I crave a few lines of your space to correct a statement on this subject by Mr. D. B. E. Foster (Feb. 12, p. 230). The point I take exception to is this: "It is generally agreed that when the sac contains all or a large part of the liver operation is useless, as it will be found impossible for the coelom to contain all the viscera."

I have twice operated for this condition when the liver and all the mobile viscera were in the sac, and on each occasion was able to close the abdominal cavity. One patient survived and is now just over 3 years old. She compares very favourably with her identical twin. I recorded my case in the *British Journal of Surgery*, and Prof. Lambert Rogers kindly sent me notes of a case of his of complete exomphalos. If I remember rightly he recorded his case in the *British Journal of Surgery* when the child (female) was 6 years old. She looked very fit but had a double inguinal hernia.—I am, etc.,

Great Yarmouth.

LEONARD LEY.

### Functions of Industrial Medical Service

SIR,—The article on the supervision of pregnant women in factory employment (Jan. 22, p. 108) aroused my interest and, in addition, my admiration for the manner in which the authors, Mr. J. V. O'Sullivan and Dr. L. B. Bourne, so deliberately ignored all difficulties in establishing their factory ante-natal clinic. As an industrial medical officer I was at first tempted heartily to agree with their conclusion that such a clinic is advisable nowadays, although not entirely because it saved the women "time, money, and many working hours," for even in this age of economic factors above all others we, as a profession, will surely concur that the welfare of the individual is not necessarily enhanced by these material considerations. One factor that has already influenced it, and will do so even more in the future, is the relationship between members of our profession, and from my own point of view I am thinking particularly of the co-operation which must exist between the industrial medical officer and the general practitioner, whose patients should be our constant interest and concern during their hours of work. It is furthermore generally agreed that in this country at any rate their welfare in industry will vary with the extent of our treatment services, and that the latter will best serve their purpose in an industrial medical service when they are reduced to a minimum. It is not the function of an industrial medical service to duplicate the work of either the general practitioner or other medical services.

I am therefore perplexed and worried to find so little reference in this admirable paper to the methods which the authors adopted to ensure co-operation with the general practitioners of those women who were seen and treated. We are told that at the first interview "the patient's local practitioner is informed that this patient has sought advice, and she is then booked to see the consultant at his next visit." In addition, apparently, when she so desires it she is sent to whatever hospital she chooses with a covering letter, and this is all done without waiting for the consent of the patient's doctor, or seeking his advice, particularly as to whether his patient should be confined in hospital or at home. After that it is not so surprising to read that "later, the scheme was enlarged to include the treatment of gynaecological cases." But surely this is contrary to every concept of an industrial medical service, and in frank opposition to the suggestions in the ethical rules drawn up by the B.M.A. for these services.

It may be that I have misinterpreted this paper, but it seems very probable that similar impressions to mine have been created in the minds of others who read it, and it is therefore only right that they should be corrected. A factory ante-natal clinic is to my mind such an ideal addition to any industrial medical service, provided it works in close co-opera-

tion with (or as part of) such clinics already provided by the public health department, that enlightenment of the problem by Dr. Bourne would be very much appreciated. The treatment of gynaecological cases, however, is a different matter altogether and is certainly not one of the accepted practice of an industrial medical service as I know them.

D.S. Medical Officer Imp.

### Bone-marrow Infusions

SIR,—I have read with great interest Mr. E. H. Bailey's review article on bone-marrow infusions. The following points about infusions in infants may be of interest, as the technique is found the most useful in these cases differs somewhat from the one described by Mr. Bailey for adults.

The cannula used was 1 in. long and of 17 gauge wire gauge. The point was bevelled like that of a fine-puncture needle, and I found it easier to get down the bone was penetrated with this cannula than with a cannula sent was used. The handle was fixed to the needle, and was removed with it after the introduction of the cannula so that the weight of the handle need not be supported by the bone. I did not find the use of a metal guard or of "wings" possible, as their sustained pressure is more than the skin of these dehydrated, marasmic infants can stand. In one case where I used a guard the skin became necrotic underneath it after two days. In all later cases I found a "naked" needle quite satisfactory and firmly fixed.

After two or three days the cannula will become loose and has to be removed. It is rarely necessary to persist any longer with the infusion. If the needle is left longer some of the fluid will ooze out of the marrow cavity into the subcutaneous tissue, and in one case where this happened the patient developed osteomyelitis. It was the only case in over forty infusions, and I believe it could have been prevented if the cannula had been removed earlier. It cleared up after surgical treatment. Considering the high susceptibility to infections of these infants, all of whom were almost moribund on admission, one must admit that the danger of producing osteomyelitis is small.

To fix the leg for the infusion we used a foot-and-leg splint reaching half-way up the thigh. It was made of 1-in. Cramer wire. A short cross-piece was fixed under the heel of the splint to prevent rotation of the leg, and a sausage-shaped bag filled with shot was bandaged between splint and padding. This made the splint so heavy that the infant could not move it. The cannula was introduced on the medial side of the tibia just below the level of the tuberosity, and no further fixation was necessary except the application of a sterile dressing around it. The advantages over intravenous infusions are the considerable saving of time and the ease with which the infant can be moved afterwards without fear of displacing the cannula.—I am, etc.,

G. BEHR.

London, N.W.2.

### Shock Therapy

SIR,—Dr. Winnicott asks for the opinion of general practitioners. Few of us will feel competent to discuss the value of shock treatment, because we have not watched enough cases over a sufficient period of time to have reached conclusions. It is quite clear that marvellous immediate results are being obtained in many cases. These make it clear, I think, that the treatment is justified in all cases judged to be "incurable" by less drastic means. Provided I feel I can trust the clinical judgment of the psychiatrist concerned, I advise my patients to undergo the treatment without hesitation.

I realize, however, that nearly every "new treatment" that has appeared during the last 30 years has been shown ultimately to carry a poisonous barb in its tail! I anticipate that within 10 years the same will prove true of shock therapy. I expect that it will be found that just as epileptic fits (and the bromide-phenobarbitone treatment) cause a degree of deterioration in the personality, so also will shock therapy. In a disintegrated personality this deterioration may be of no moment, but if the treatment were extensively used for cases that could be cured by less drastic means needless harm would have been done. Particularly, I foresee a danger that shock treatment

should come to be used as a "short cut" to the abolition of mental symptoms. Surgery can be used in a similar fashion. If shock treatment were ever employed or advocated, either because there were not enough trained psychiatrists to devote personal and individual care to individual cases or because the facilities for cultural, occupational, and recreational therapy were inadequate in the hospital, then shock therapy would be an unethical form of treatment.

From my own experience I endorse Dr. Winnicott's statement that the vast majority of children who manifest the schizophrenic, depressive, paranoic, and hypomanic types of personality recover spontaneously under right management. If that were not the case our mental hospitals would be still more crowded than they are. I hope most sincerely that the utmost caution will be exercised in the use of shock therapy (or any other form of drastic treatment) for children. I believe that child psychologists and psychiatrists ought to co-operate with educationists and those concerned with delinquents to investigate the "norms" of child-personality and its commoner deviations. When the "norms" have been determined it would be possible to judge whether a form of treatment that may damage mental function and even nervous structure can be justified in any particular instance.—I am, etc.,

Worcester

HOWARD E. COLLIER.

### Shock Therapy: A Personal Experience

SIR,—I have read the letters on electric convulsive therapy by Dr. Winnicott and others with interest and amazement at some of the opinions of the effect on patients. Some first-hand experience as a patient may clear misgivings.

As a student and doctor I felt some awe at the stories I heard about shock therapy and was glad I was not the patient. Since then I have suffered a severe reactive melancholia, a doctor was called, and I was persuaded to undergo treatment at a progressive mental hospital with a tradition of humane treatment of the mentally ill. In spite of continuous narcosis and then psychotherapy I became worse, and after six weeks I gave notice of leaving. It was then decided to try convulsive therapy, which was used extensively at the hospital, and my wife (the only person whose honesty I trusted) persuaded me to stay for it. Being melancholic I was very fatalistic and was always waiting for the worst. I walked to the room, feeling, I suppose, like a murderer going bravely to the gallows and interested in the mechanics of the apparatus. I do not think it was a wish for death, as I never wanted to die, but had only thought of life for myself as being impossible. When a soldier feels there is no alternative but to charge the enemy guns, and that his life or death is out of his hands, that is surely not a wish for death.

The psychotherapist was experienced and business-like about the treatment. I lay on the bed, pushed my feet against the pillow, had the electrodes clamped round my head, bit the pad between my teeth, and relaxed. I remember feeling, even then, it was an experience that might be useful to have. Also, what seems very important, I felt that something really was being done, and that I was a real patient and not only a contemptible fraud who had no right to be off work. When the current was switched on I felt nothing; it was just like going to sleep without sleepiness. Later I woke up back in my bed, collected my diseased wits, and in a few minutes realized I had had the shock therapy. Although my logic and reasoning were the same and seemed never impaired, my melancholic perspective of myself had changed—rather like a child wakes in the sunlight after a midnight thunderstorm with the same parents and home round him. I remembered quite quickly everything leading up to the so-called shock. Nurses and family noticed a miraculous improvement.

The following "shocks" were at greater intervals. Although I knew exactly when to expect the loss of consciousness, I could never detect it happening. As the intervals between each dose drew to an end I was able to detect a change of mood for the worse, which would be magically dispelled by the next "shock." It was too subtle a retrogression to describe and I never tried to tell others of it. I saw other patients brought back from the treatment, some unconscious and some in chairs. They looked pitiable sights, but if they were like me they knew nothing of it themselves. The only mild discomfort

was that of vomiting once after the first of the nine doses.

I was at the hospital three months and convalescent three months after. When I left the hospital I was still ill (I never then believed they would really let me out without one or other of the staff punishing me with some torture, if only on the last night). My memory of the hospital is not at all a happy one, though I realize I was treated as well as any mental patient is to-day; but I can quite honestly say that the bogey of electric convulsive therapy as imagined by some psychologists was not one of my bogies; though there were many I knew. No one suggested that shock therapy was a complete cure in itself, but it cut short my period off doctoring by at least three months. Purely selfishly I would prefer shock treatment itself to gas or ether anaesthesia or to dentists' drills, and no one has suggested that they are not "ethical."—I am, etc.,

"DOCTOR-PATIENT."

### Diet in Hospital

SIR,—From my own limited experience I heartily endorse the view expressed in the second paragraph of his letter on p. 690 of your issue dated Nov. 27, 1943, by Wing Cmdr. H. M. Stanley Turner so far as civil and military hospitals in India are concerned. I have never understood the rationale of doping patients with drugs and starving them of the necessary salts, vitamins, amino-acids, etc., which would be present in a well-balanced and properly cooked diet. A hospital kitchen should be in charge of a competent "chef," and all modern arrangements for bringing the food rapidly and in excellent condition from the kitchen to the wards should be perfected. I was in the process of proving by statistics the value of the close supervision of the diet on the death rate and the length of stay in the hospital of prisoners in a jail hospital when the work was interrupted by military service. My figures remain as a result open to the objection that the period covered was not long enough to exclude the influence of climatic variations, etc.—I am, etc.,

Poona.

F. R. W. K. ALLEN.

### Regulation 33B

SIR,—Your leading article on Regulation 33B (Feb. 12, p. 223) seems to suggest that the real meaning of the regulation is not to compel treatment but to suggest it—persuasion, not compulsion. Well, Sir, if this regulation is not meant to compel infected prostitutes to obtain treatment then the public has been very much misinformed, and the public will be very much disappointed. I am all for the *suaviter in modo*, but let it be followed by the *fortiter in re*.

In the House Miss Horsbrugh said that the figures quoted by Dr. Summerskill (2 men and 64 women) were of those who had refused treatment and on whom a notice had been served. What was the fate of these 66 people? How many presented themselves for treatment? How many were prosecuted? Why not tell the public these things? Miss Horsbrugh also said that medical officers had had an idea that if they "interviewed people and asked them whether they were aware they had this disease there might be subsequent actions for slander."

Miss Horsbrugh was referring to medical officers of V.D. clinics she is wrong. No medical officer of a V.D. clinic would commit himself in that way *before* examining the patient. If, however, she was referring to medical officers of health, there was no need for them to interview these contacts. The fear of legal proceedings arose when a health visitor interviewed a contact on the evidence of one informer only. To safeguard the authorities the Minister "is using the power Regulation 84 gives him to permit disclosure," as you say. So we can get on with the *suaviter in modo*.

You say "the elaborate and rather repulsive procedure for compulsory examination and treatment is hardly ever used." Sir, the procedure is neither elaborate nor repulsive. It is simplicity itself. If two persons inform against a contact the V.D. officer completes Form I and sends it to the medical officer of health, who thereupon requires the contact to submit to examination within ten days. The reason this procedure is so seldom used is that, in my experience (and as I pointed out in my letter to the *Journal* of Jan. 2, 1943, p. 21), in civil life it is most exceptional to find two patients who are able and willing to testify to infection from the same source,

and it is not possible, therefore, to comply with the requirements of the regulation. And so the *fortiter in re* does materialize.

One word about the high incidence of syphilis. There is going to be a terrible harvest of congenital syphilis if steps are not taken in time to prevent it. If the Ministry of Health were to issue instructions to all health authorities to make a routine Wassermann test a part of all ante-natal examinations we should go a long way towards prevention. No Act of Parliament is required for this.—I am, etc.,

Treatment Centre, Royal Infirmary, Sunderland. NOEL F. ROWSTRON.

### Principles of Reform in Medical Education

SIR,—Dr. F. M. R. Walshe's article (Feb. 5, p. 173) comes as an invigorating and provocative stimulus to those of us interested both in the training of medical undergraduates and in the future of the theory of medicine. I wish to make two points only, the first, a particular one, concerning the teaching of psychological medicine to students, and the second, a more general one, in reference to, as he puts it, "old branches of medicine that have taken new names and adopted new slogans."

I am grateful to Dr. Walshe for saying that the "wise infusion of medical education by the principles of psychological medicine demands something more fundamental than the compilation of a long list of titles of lectures and appointments." He has laid his finger on the weakness of many psychotherapists' teaching to students, who claim this teaching as their province and at the same time work alone. I am already convinced that this infusion can be obtained without adding to the curriculum at all. The material is there in the general hospitals, but with few exceptions the teachers are not. I find in my weekly out-patient clinics I have seen during the last 12 months 125 cases of psychoneurosis out of a total of 420 new patients in the general medical clinic, and 17 out of 312 in the neurological clinic; in my wards also many patients' recovery is delayed by their unfortunate emotional reaction to organic illness. I am sure such figures are general and I feel that adequate postgraduate training in psychological medicine would ensure that this material could be successfully used by physicians in the course of their general medical teaching. This reform might at last destroy the prejudice that makes a Babinski response more interesting and more worthy of therapeutic attention than a flood of tears.

Dr. Walshe pleads for forthright precision in language and thought, suggests neurology and cardiology as the forms of medicine in which teaching has emphasized disordered function and attacks psychological medicine for its internal conflicts: its state of fermentation, and its incoherence. At least its leaders have usually recognized that diseases are not concrete things. Dr. Adolph Meyer in 1906 in the columns of the *Journal* defined mental illnesses as reaction states and first correlated personality with psychosis. For clarity, coherence and forthright precision I should like to quote a more recent authority. "Psychoneurotic persons are potentially 'normal' persons, in whom the reaction to life is overly tense, overly symbolized, unhealthy, and disturbing. Psychotherapy should be directed at removing excessive stress, eliminating immature and unhealthy personality traits, and substituting mature and healthful reaction patterns with which to meet any future stresses."<sup>1</sup>

My second and more general point briefly concerns the dangers of adding specialized courses to the curriculum. There is a tendency in medicine to-day to turn away from disease to health, which I believe to be essentially right and long recognized as necessary by many of us. This concept must run like a thread through all clinical teaching and bind medicine together in one progressive whole. The creation of so many new departments rather than the reform of the old suggest an unfortunate cleavage of the profession into those who, for example, teach social medicine rather than clinical medicine. I await uneasily the possible election of one of our number to a "chair of rehabilitation"—another professor, another department, another course. Perhaps, however, better-adjusted endowments will one day spread more widely clinical professorships and so even up our universities in this respect.

<sup>1</sup> *The Therapy of the Neuroses and Psychoses*, by S. H. Knapp, H. K. Kingston, London, 1943.

Finally, let us by all means take the students to the factories, to the welfare clinics, to the schools, to the special hospitals and health centres, but do not let us add "courses" to their clinical work, and do ensure that we teach them that all medicine is social, all health positive, and all treatment rehabilitation.—I am, etc..

A. BARIAM CARLIS

Staines County Hospital, Ashford, Middlesex.

SIR,—The masterly article by Dr. F. M. R. Walshe (Feb. 5) shows that it will not be possible in the future for a conscientious student to master as much of the subjects in the time allowed as his teachers will require. Therefore for qualification in a reasonable time we shall have to arrange for a degree or diploma to be given much earlier, say, after 3 or 4 years, and the specialties to be studied later, if so desired. The student will have to be given courses in medicine, surgery, etc., equivalent to first-aid classes, lasting, say, a year in all. Of the preliminary sciences he need know little more than he may have learned at school, provided by then he has learned how to work. Our next care should be to see that his brains and memory are preserved, not shattered, as is so often the case at present. For instance, why need he know the intricate details of all pathology? Conversely it is not really necessary for a medical pathologist or bacteriologist to be a doctor. There should be no examination system because it spoils the mental outlook and interest in a subject, but rather an apprenticeship with reports by the teachers as to when the student may be released to the departments where there are patients. At this work he should remain for two years, and again by report become a qualified doctor. The succeeding years of practice and experience may then be partly occupied with progress in any desired subject with a view to specialization. For under such a scheme there would have to be specialists.

It has always seemed to me that in the past we have planned our courses and teaching in a wrong manner. Both should be based, or largely based, on the frequency of disease. Certainly the probability of the condition being met with in practice should be stressed. The student's mind is by nature a collector of rarities, useful, no doubt, to solve a difficult scientific point, but otherwise just interesting mental junk. Lately a doctor asked his locumtenent to treat a man with a cold, but the locumtenent said quite seriously that he would prefer to have a case of leprosy if one were available.

Then again, why need a factory inspector be a doctor? Such a functionary only needs to be able to see where and why dirt or infection lies, or how such-and-such a nuisance or infection or accident may be prevented. In the proposed scheme he would get there earlier and qualify for a pension sooner than if he had to undergo a minimum training of 5 years. But I maintain he need not be a doctor!

The modern trend of psychological study and a desire to imbue doctors with it, though in the past the results without its prevalence have really been excellent, should, I think, be resisted until psychologists are able to describe their cases in language that can be understood by the average man.

Briefly, the total quantity of technical matter to be inculcated and absorbed to-day is so vast that the task becomes impossible if the mind is to survive. We shall have to approach the whole business in a new way somewhat as indicated above. This course would tend to foster reflection and research in a proportion of students.—I am, etc.,

London, W.1.

G. H. COLT.

### The General Practitioner and Physical Medicine

SIR,—During and following the last war the value of physical medicine as an adjunct in the treatment of various illnesses was proved. For some reason or other its value was forgotten, or at any rate was relegated to the limbo of forgotten things. During this war physical medicine is again taking its rightful place, and our men and women of the Forces are being trained gradually to appreciate its value and its limitations. On their return to civil life they will expect the same efficiency. I think we should now consider these future problems, for we shall have to face them when peace comes. The general public, too, is getting to hear of physical therapy and is appreciating its value.

Physical therapy employs massage, exercises, various forms of heat, and other externally applied treatment. It has become a major part of the rehabilitation programme for the war-wounded, and centres are already established in various areas over the country. General practitioners should be given an opportunity to attend lectures and practical demonstrations dealing with the various modalities used in physical medicine. They would see how, particularly in the rheumatoid diseases (but not only in these conditions), the response of the patient is proof of their efficacy. It is high time that we had a centre for postgraduate instruction, similar to those centres which exist in the U.S.A. The general public must be educated too. General practitioners who are interested and undergraduates who are being sent out from the various colleges should make their patients "physico-medically" conscious, and in this work our able "Radio Doctor" can be of enormous help, as well as our newly formed British Association of Physical Medicine.

The time has come when the patient should no longer be sent to the hospital out-patient department with the note, "Will you kindly arrange for electrical treatment," because the patient prevailed upon the doctor to do so. The doctor must know when physical therapy is indicated and when it is contraindicated, for it is only then that we can truly say to our patients that we have used all the medical armamentarium at our disposal. If we could find some philanthropist and eminent adviser to our Government who could come to our help so that a survey of the whole field of physical therapy could be carried out under a chosen medical committee, we would then be in a position to widen its usefulness in the prevention and cure of illness. The ethical development of physical medicine as a part of organized medicine lies in the hands of the general practitioner.

The types of patients treated are those with musculo-skeletal injuries seen in civilian life, back injuries, sprains, strains, dislocations, together with fractures, burns, etc. The steady return of war casualties will constitute a need for trained general practitioners, able to guide and advise as to the treatment necessary for the condition present. This need will increase and we must be prepared.—I am, etc.,

London, N.13.

MYER FISHER..

### Control of Pharmacological Products

SIR,—There are already signs that the manufacturing chemists are planning to exploit or "develop" (in the trade sense) the sulphonamides, as they have in the past exploited the barbiturates. War conditions are at present hindering this tendency, but as soon as peace is restored it seems certain that exploitation will increase unless some control is instituted.

The process of "development" is only too familiar: the firm's chemist produces a slight variation of an existing compound (a relatively easy matter in organic chemistry), next a very inadequate clinical trial is staged—often by the offer of free supplies—the compound (with a fancy name) is boosted by every device of the firm's advertising department, until, finally, the "sales resistance" of the practitioner perforce collapses.

Before this bewildering array of good, bad, and indifferent remedies is thrust upon us action should surely be taken, and now is the time while the condition is still "operable." Either the Ministry of Health or the Medical Research Council or the Pharmacopoeia Commission could institute a sufficient measure of control that would benefit the community as a whole.—I am, etc.,

Moor Park.

ROBERT C. TAYLOR.

### Stinging Fish

SIR,—In the review of Dr. Muir Evans's book *Sting-fish and Seaferar* (Feb. 5, p. 186) mention is made of the black scabbard fish. As it is little known here it may be mentioned that under the name of "espada" it is frequently served up in the hotels of Alameda, and in the fish market at Funchal I saw several for sale. Elongated, black, and glistening, the fish suggest lengths of india-rubber, and they are frequently carried borne tail to mouth, suggesting so many tyres. They inhabit the ocean abyss at depths of more than half a mile, and have the large eyes so characteristic of deep-sea fauna.—I am, etc.,

Manchester.

GRAHAM RENSHAW.

## Obituary

FRANCES IVENS KNOWLES, C.B.E.  
CH.M.(Hon.), M.S., F.R.C.O.G.

Mrs. Ivens Knowles (Miss Frances Ivens) died on Feb. 6 after a brief illness. She had been a member of the B.M.A. for 43 years, was vice-president of the Section of Gynaecology and Obstetrics at the Annual Meetings of 1912 and 1920, and served on the Ministry of Health Committee of the Association; she was also a member of the Consultative Council on Medical and Allied Services set up by Lord Addison, the first Minister of Health. A colleague sends the following account of her career:

Mary Hannah Frances Ivens studied medicine at the Royal Free Hospital and in Dublin and Vienna, and graduated M.B. with honours and gold medal at the University of London in 1900. She took the M.S. degree three years later, and had seven years' surgical experience in London before she was appointed in 1907 gynaecological surgeon to a new unit in the Liverpool Stanley Hospital—the first woman to hold an honorary post in a Liverpool hospital. There she built up a large gynaecological out-patient department, and kept her ward beds filled with patients, who still testify to her care and skill. Later she was also appointed honorary surgeon to the Liverpool Samaritan Hospital. Then came the last war, when she volunteered at once for service in Belgium, but had to return without landing. In December, 1914, she went to France as head of the unit of the Scottish Women's Hospital, which worked in the Abbaye de Royaumont under the French Red Cross. Miss Ivens devoted her great energy to this hospital, and soon the excellence of her work for the wounded French soldiers was recognized by the French Army, and to it the hospital became attached and was known as the Hôpital Auxiliaire d'Armée Française, 30, the beds being increased from 100 to 600. She continued as *médecin chef* till February, 1919, with only one period of leave in England, which she spent largely in lecturing to raise money for the hospital. In 1917 she was asked to open another hospital at Villers Cottreets. There she operated under shell fire during the German advance in March, 1918, until the approach of the enemy forced her to evacuate back to Royaumont. In recognition of these services she was decorated by the French President with the Cross of the Legion of Honour. In addition she received the Croix de Guerre with palm and the Médaille d'Honneur des Epidémies. This work in France was an outstanding achievement. The hospital had a great reputation, was inspected and approved by many French generals and Government officials, and this success was certainly due to the personality of its head and the devoted support she inspired in her staff.

After the war Miss Ivens returned to her hospital and large consultant practice in Liverpool, and threw herself with energy and enthusiasm into several new ventures. Chief among these was the rebuilding of the Maternity Hospital, to the honorary staff of which she had been appointed, the formation of the Liverpool and Women's Radium League, and the opening of the Crofton Recovery Hospital for Women. For these public services she was made a Commander of the British Empire in 1929, and Liverpool University bestowed the degree of honorary Ch.M. She always entered whole-heartedly into the local medical life, sat on numerous committees and spoke her mind, read papers at the Liverpool Medical Institution and North of England Obstetric and Gynaecological Society, wrote articles for the Press, and published a book on Caesarean section.

In 1930 she left Liverpool after her marriage, but continued a consultant practice in London till she and her husband retired to their home in Truro. However, her mental alertness and her excellent physical health did not allow her to rusticate. She served on hospital and Red Cross committees, took a part in the social life of the county, and did a great deal of hard work in the garden. She took to war work again in 1939, acting as medical inspector for the Red Cross in Cornwall and organizer of liaison officers who are looking after the

welfare of soldiers and their relatives. All this she was doing up to the time of her death.

Mrs. Ivens Knowles was a woman who led an active, busy life, but she had time for social functions, which she thoroughly enjoyed, and was renowned for her hospitality and charm as a hostess and conversationalist. It delighted her to give parties for those who were working with her in hospital or to take them to the theatre. She kept up her connexion with France by paying holiday visits to different parts of the country, by belonging to a French society where she met and conversed in their language with those French people living in Liverpool. Many of the "blessés" who had been in her hospital in France wrote regularly, and she met members of the staff at the annual dinner of the Royaumont Association, of which she was president, and just before her death she was doing propaganda work for the "Friends of France." She took an active part in the Medical Women's Federation, was president for a term of two years, and chairman of subcommittees, and was always ready to help and give advice to young medical women.

This long and full career was sustained throughout by unflagging mental and bodily vigour. She expected much from those working with her, and got it because she always did her share. Her kindness and sympathy to her English and French patients were rewarded by the admiration and devotion they showed for "the Lady Ivens" and "La Colonelle."

Dr. JAMES H. ORMOND died suddenly in his sleep on Jan. 9 at his residence at Lozells, Birmingham. He was aged 75. Educated first at Partick and Glasgow Academy, he graduated M.B., Ch.M. at Glasgow University in 1893, and after some years in general practice in Glasgow he settled in Birmingham in 1900, and worked for 44 unbroken years in general practice. Despite his advancing years, and quite unshaken by severe air raids in his area, Dr. Ormond carried on as usual, and it may truly be said that he died in harness.

Sir GOULD MAY, M.A., M.D., M.R.C.P., who died on Feb. 12 in his 81st year, was one of the distinguished sons of the late Right Hon. George May, Lord Chief Justice of Ireland. Educated at Rugby, Trinity College, Cambridge, and the London Hospital, Gould May had during a long career an extensive and very successful private practice in Belgravia. He was especially interested in gynaecology, and was for many years physician, to and later consulting physician to the Grosvenor Hospital for Women, Vincent Square, and to the St. George's Dispensary, Pimlico. During the last war the British Red Cross Society organized a hospital to work among our allies in Russia, and to this Gould May was appointed physician and the late Sir Herbert Waterhouse surgeon. On the return of this hospital to England Gould May became senior medical officer to the Russian Hospital for British Officers in South Audley Street, a most successful and popular hospital financed by a Russian lady, Madame Mouravieff Apostol. Gould May was knighted in 1923 on the recommendation of the Prime Minister, Mr. Bonar Law, whom he had attended for many years; he was also a Knight of Grace of the Order of St. John of Jerusalem. "Gouldie" was a keen sportsman and an expert fisherman, deservedly popular for his generosity and kindness of disposition among a large circle of friends.—A. M. W.

The late Dr. E. WINIFRED DICKSON was born in 1866 at Dungannon, Co. Tyrone, and educated in Belfast and London. After nursing her mother for a year she decided, with her father's encouragement, to go in for medicine. The School of the College of Surgeons in Dublin was just opened to women, and this she entered in 1887. She found that she was apparently capable of passing examinations easily, and, anxious to obtain a university degree, she applied for permission to enrol at Trinity College. Though supported by the medical faculty she was unsuccessful, owing to the opposition of the theologians. She therefore matriculated in the old Royal University of Ireland, and, carrying on both courses simultaneously, took her licentiate in 1891 and the M.B. in 1893, the latter with first-class honours and an exhibition. In the same year she was elected the first woman Fellow of the Royal College of Surgeons in Ireland and won a travelling scholarship on which she studied for six months in Vienna and Berlin. While abroad she applied for a resident post at the Rotunda, but the managers refused to appoint a woman. On her return to Dublin she put up her plate first in St. Stephen's Green and then in Merrion Street, and was appointed gynaecologist to the Richmond, Whitworth, and Hardwicke Hospitals, and assistant master of the Combe

Lying-in Hospital. In 1896 she took the M.D. and the membership in obstetrics, both with honours, and was appointed an examiner in midwifery to the Royal College. She wrote a number of papers in her specialty, but her interests were not confined to it. She married towards the end of 1899 and unlike some of the feminists of the day, decided that she could not continue to practise. In 1915, however, with her husband on service and her children at school, she came back first as an assistant in Rainhill Mental Hospital, and later as a war deputy at Ellesmere, Shropshire, where, in addition to general practice, she acted as M.O.H., and visited the local service convalescent hospitals. Later she bought the practice and took on a more active assistant, but in 1919 an attack of bronchopneumonia forced her to give up this. Thereafter medicine took second place to the needs of her family, but she spent two years in practice in London, at Siena, Italy, and at Leobach, West. In 1930 illness again made her stop for a time but for several years she went to South Wales as a part-time clinical assistant to a mining community for whom, and more especially for the womenfolk, she had the greatest sympathy. Twenty-five years after her first wartime locumtenency she was again called to the staff at Rainhill, and there she continued to follow duty up to within two months of her death at the age of 77. She can be numbered among the pioneers who helped to remove the prejudice against women in the profession and so made it easier for those who have followed her. A correspondent writes: I only met Dr. Dickson in her old age but there was a vigour and vitality about her and a directness of opinion and expression which are unusual and refreshing. With this strong personality went a very remarkable unselfishness, and it was characteristic of her that, knowing for several months that she had an incurable carcinoma, she not only made no mention of it to her family but continued with her work until within a few weeks of her death.

## Medico-Legal

### AN M.O.H. VINDICATED

Acknowledgment that statements made by her against Dr. Adam Douglas Fraser Menzies, medical officer of health for Skegness, were entirely without foundation was made by Dorothy W. Hunter, former matron of the Skegness and District Hospital, in an action for slander brought against her at Lincolnshire Assizes. Hunter unreservedly withdrew any charge she might have made affecting the character and reputation of the plaintiff, and further stated that she had no justification for making any such charge. She submitted to judgment and to an order to pay Dr. Menzies his taxed costs of the action. Through Mr. C. L. Henderson, K.C., she expressed her profound regret to Dr. Menzies for the injury he had sustained by reason of the matters complained of in the action.

Mr. Arthur Ward, K.C., who, with Mr. J. P. Stimson (instructed by Messrs. Le Brasseur and Oakley on behalf of the London and Counties Medical Protection Society), appeared for the plaintiff, stated that the slanders were of a very serious nature. Dr. Menzies, a surgeon of 17 years' standing, was a member of the staff of the hospital where Hunter was the matron. Fortunately the doctor suffered no professional injury as no one who knew him believed the slanders. The sole purpose of bringing the action, since Hunter submitted to judgment on terms which had been agreed, was to vindicate his character.

Mr. Justice Charles said he was very glad indeed that the action, which was of a most serious nature, had been thus settled. Most shocking allegations, to which he was not going to refer, were made against a doctor of high reputation not on one occasion, nor two, but on three occasions. These allegations had been made, he imagined, deliberately, after consideration. "If these statements had been true," he continued, "and I now understand that they are a pack of lies, the duty of the defendant, who was a matron of a hospital, was to go direct to the police, for an allegation was made of a very serious criminal offence. How on earth a person in that position could, if she be in her right mind, have made a series of serious allegations against the medical officer of health, such as she did make, when she knew all the time that they were totally untrue—and now by her counsel openly in this court does say so—is quite inconceivable to me. I am very glad indeed that she has seen sense, and some sense of decency, at last."

The statement unreservedly withdrawing any charge Hunter might have made affecting the character and reputation of the medical officer was read by Mr. Henderson. The judge commented that he was satisfied with this statement, which, he said, amounted to unreserved withdrawal, admission that the statements were untrue and without foundation, and an expression of regret. Judgment with costs was given for Dr. Menzies.

## Universities and Colleges

### ROYAL COLLEGE OF SURGEONS OF ENGLAND

#### BUCKSTON BROWNE LUNCHEON

The Buckston Browne Luncheon for Fellows and Members was held on Saturday, Feb. 12 (the eve of the 216th anniversary of John Hunter's birth), in the Great Hall of Lincoln's Inn with the President, Sir Alfred Webb-Johnson, in the chair, and for the second time lady Fellows and Members formed part of the large company. The guests included five members of the Government—Lord Woolton, Mr. Ernest Bevin, Mr. Henry Willink, Captain Crookshank, and Miss Florence Horsbrugh—and all were received in the ante-chamber by the President and the two Vice-Presidents, Mr. H. S. Souttar and Sir Gilling Ball. Before the assembly sat down a loyal message had been sent to the King as Visitor of the College, and afterwards an acknowledgment was received from His Majesty. The Princess Royal, an Honorary Fellow of the College, also sent a message, as follows: "Her Royal Highness the Princess Royal deeply regrets that she is prevented from being present in person at the luncheon to-day, but her thoughts will be much with all the Fellows and Members, and with their President. She has a lively recollection of the delightful occasion on which she last attended the Buckston Browne Luncheon and of the pleasure which it gave her, and she sends to all present her very best wishes and remembrances." After lunch, when the loyal toasts had been honoured, Mr. Souttar presented Mr. W. H. Collins for the award of the Honorary Medal of the College in recognition of many liberal acts, and particularly his great generosity in the endowment of the Department of Pathology in the College and the institution of a Chair of Human and Comparative Pathology.

The President's speech of general welcome and review of events passed from grave to gay and back again with his customary skill. In a reference to the Beveridge report and the forthcoming White Paper he said that the Royal Colleges had a special responsibility in regard to the consultant services and the standards to be required; their higher diplomas were accepted hall-marks throughout the Empire. For a generation the medical profession had been pressing for a comprehensive medical service for those in need of it. No one knew better than they the ravages of want. They therefore welcomed the Government's decision to provide this service, and if it were provided only for those who could not provide it for themselves half the difficulties would disappear. On behalf of the Council he greeted the five Ministerial guests and warmly thanked the Treasurer of Lincoln's Inn, Judge Sir Gerald Hurst, for his courtesy and that of the Benchers in lending their magnificent hall to their surgical neighbours and friends in Lincoln's Inn Fields. Among those he named as having honoured the College by their attendance that day were Sir Henry Dale, President of the Royal Society, Lord Moran, President of the Royal College of Physicians, Mr. Eardley Holland, President of the Royal College of Obstetricians and Gynaecologists, Sir Stanley Woodward, Master of the Society of Apothecaries, Sir Herbert Eason, President of the General Medical Council, Sir Henry Tidy, President of the Royal Society of Medicine, and Dr. H. Guy Dain, Chairman of Council of the B.M.A.; Surgeon Vice-Admiral Sir Sheldon Dudley, Medical Director-General R.N., Lieut.-General Sir Alexander Hood, Director-General, A.M.S., Air-Marshal Sir Harold Whittingham, Director-General, R.A.F.M.S., and Major-General Sir Ernest Bradfield, Medical Adviser to the Secretary of State for India; also Sir Edward Mellanby, Secretary of the Medical Research Council, and Sir Wilson Jameson, Chief Medical Officer, Ministry of Health, and the following representatives of Allied and Friendly Nations: Brig. Paul R. Hawley, Col. Elliott C. Cutler, and Col. J. C. Kimborough (U.S. Army Medical Corps), Capt. W. M. Anderson (U.S. Navy), Major-Gen. R. Lutton (Canada), Lieut.-Col. J. H. Anderson (Australia), Prof. S. Sarkisov (U.S.S.R.), Dr. Woo (China), Dr. H. A. Aksel, Lieut.-Col. B. Tugan, and Dr. Bekir Taskiran (Turkey), and Dr. Alvaro Pontes (Brazil).

The Minister of Health, Mr. Willink, in a serious speech lightly delivered, spoke of the affinities and common ideals of medicine and his own profession of law, of the family bonds which join him to doctors, and of his wish for full co-operation with the profession of medicine. Whatever the coming White Paper might contain they could rely on him to listen most carefully to what came from the R.C.S. and the sister Colleges. In everything that the Government would put forward for consideration and discussion probably nothing was more important than making the benefits of medical science available to every member of the community.

The last toast, proposed by Sir Gilling Ball, was that of the health of "the founder of the feast," Sir Buckston Browne, now nearing his 93rd birthday, whose vigorous reply, paying tribute to Hunter and Jenner and Lister, could be heard in every part of the hall.

## ROYAL COLLEGE OF SURGEONS OF ENGLAND

An ordinary meeting of the Council of the College was held on Feb. 10 with Sir Alfred Webb-Johnson, President, in the chair. Surg. Rear-Adml. G. Gordon-Taylor was appointed Thomas Vicary Lecturer for the year 1944. Mr. P. J. Moir, Mr. N. Sinclair, Mr. W. D. Doherty, Brig. A. H. Whyte, Surg. Cmdr. J. B. Oldham, Mr. B. H. Burns, and Surgt. Capt. Lambert Rogers were re-elected, and Mr. T. Twistington Higgins and Air Cmdr. Stanford Cade were elected Members of the Court of Examiners. Mr. W. Kelsey Fry was elected a Member of the Board of Examiners in Dental Surgery for three years as from March 9. The following were elected Examiners in Applied Physiology and Pathology for the Fellowship for the remainder of the Collegiate year 1943-4: Prof. R. J. S. McDowall and Prof. Samson Wright (Physiology); and Prof. Geoffrey Hadfield and Prof. W. G. Barnard (Pathology). Mr. Eardley Holland was reappointed as the representative of the College on the Central Midwives Board for a further year, as from April 1, 1944.

A Diploma of Fellowship was granted to W. H. Bond. Diplomas of Membership were granted to A. Brown, T. R. Farrimond, J. L. McKelvie, R. Milton, E. S. Shalom, T. R. Steen, M. J. Williams, and to the list of candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London in the *Journal* of Feb. 12 (p. 239).

## UNIVERSITY OF BIRMINGHAM

The following degrees were conferred *in absentia* on Dec. 18, 1943, by special warrant:

M.D.—1 D. R. Humphries, C. F. V. Smout, C. C. Teall.  
Ph.D.—(In the Faculty of Medicine): R. A. M. Case, A. D. T. Govan.  
M.B., Ch.B.—13 Theresa Lazar, 131. Macnab, 2 Evelyn M. Crawford, 2 Margaret L. Hampton, 2 Margaret D. Thompson, 3 Kathleen M. Brown, R. A. Chand, Beatrice D. Cluley, Joan R. Collins, Kathleen M. Fox, K. H. Freeman, Ida C. Hughes, R. A. F. Jack, R. Lindop, Mary S. McGladdery, J. C. Miller, 5 J. M. Mynors, 3 Dorothy J. M. Readman, B. V. Robinson, 4 F. C. Williams, G. F. J. Williams, P. W. Woodcock.

1 First-class honours. 2 Second-class honours. 3 Distinction in paediatrics and medicine. 4 Distinction in medicine. 5 Distinction in midwifery.

## UNIVERSITY OF SHEFFIELD

The Council at its last meeting appointed Prof. E. J. Wayne, M.D., to be director of postgraduate medical studies. Prof. J. Crighton Bramwell, M.D., and Surg. Rear-Adml. C. P. G. Wakeley, F.R.C.S., were appointed external examiners in medicine and in surgery respectively.

## The Services

The *London Gazette* has announced the appointment as K.B.E. (Military Division) of Major-Gen. (temp.) E. M. Cowell, C.B., C.B.E., D.S.O., T.D., late R.A.M.C., in recognition of gallant and distinguished services in the field.

The *London Gazette* has announced the award of the D.S.O. to Capt. (temp. Major) (Acting Lieut.-Col.) A. Crerar, M.C., R.A.M.C., and the M.C. to Capt. (temp. Major) D. L. Lewis, R.A.M.C., in recognition of gallant and distinguished services in Italy; Capt. J. J. Sumner, R.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in Burma.

## R.A.F. APPOINTMENTS

The undermentioned officers of the Medical Branch, Royal Air Force, have been granted the acting rank stated, from Jan. 16, 1944, while holding the appointment indicated:

Medical Officer	Acting Rank	Appointment
Air Cmdr. A. F. Rook, O.B.E.	Air Vice-Marshal	Consultant in Medicine
Air Cmdr. G. L. Keynes	"	Consultant in Surgery
Air Cmdr. C. P. Symonds, C.B.	"	Consultant in Neuropsychiatry
Air Cmdr. T. C. St. C. Morton	Air Commodore	Consultant in Pathology and Tropical Medicine
Acting Wing Cmdr. J. F. Bromley	Group Captain	Consultant in Radiology
Acting Group Capt. C. W. Flemming	"	Additional Consultant in Surgery
Wing Cmdr. T. K. Lyle	"	Local Consultant in Ophthalmology over-seas
Wing Cmdr. G. L. M. McElligott	"	Consultant in Venereal Diseases
Wing Cmdr. F. W. Roques	"	Consultant in Gynaecology
Wing Cmdr. R. R. Trail, M.C.	"	Consultant in Mass Radiography and Tuberculosis

## CASUALTIES IN THE MEDICAL SERVICES

Missing at sea.—Lieut.-Col. T. S. Eves, D.S.O., R.A.M.C.  
Died.—Temp. Lieut.-Col. Felix Smith, R.A.M.C.

## Medical Notes in Parliament

The Parliamentary Medical Committee has changed its title to the "Parliamentary Medical Group."

Dr. Charles Hill, Acting Secretary of the B.M.A., and Dr. George Buchan (Association of Medical Officers of Health) met the Parliamentary Medical Group on Feb. 14, explained the views of their Associations on the Education Bill, and suggested amendments. A deputation was proposed to the Minister of these amendments, and it is expected that the Group will sponsor certain which are in preparation.

Dr. Hill will meet the Parliamentary Medical Group on March 7 to discuss the White Paper on a National Health Service.

## The White Paper

Announcing on Feb. 17 the issue of the White Paper on a National Health Service Mr. WILLINK said the proposals described were those which the Government believed to be best calculated to achieve an efficient and comprehensive National Health Service. But they were proposals, not decisions, and the Government had promised that they should be discussed with all concerned and would welcome constructive criticism in Parliament and the country.

## Incidence of Venereal Diseases

Mr. WILLINK said on Feb. 10 that figures were not yet available for the year 1943 of the number of new cases of venereal diseases treated at local authority clinics. These diseases were not notifiable. Incidence of these diseases had increased since the beginning of the war, but the rate of increase had recently diminished. Regulation 33B, though this did not require statutory notification, had had an appreciable effect.

## Infant Mortality

On Feb. 10 Mr. WILLINK gave the following statement: Deaths per 1,000 live births of infants whose age does not exceed 24 hours, in England, Scotland, and Wales for the years 1935 to 1942, are as follows:

Year	England	Scotland	Wales
1935 .. ..	10.7	11.7	12.1
1936 .. ..	10.6	11.9	11.9
1937 .. ..	10.8	12.0	11.7
1938 .. ..	10.2	11.6	11.0
1939 .. ..	10.2	13.3	10.9
1940 .. ..	9.5	12.0	10.6
1941 .. ..	9.8	13.0	11.1
1942 .. ..	9.5	12.0	9.9
1943 .. ..			Figures not available

On Feb. 15 Mr. WILLINK informed Major Markham that the infant mortality rates for England, Wales, and London for 1941, 1942, and 1943 were as follows:

	England	Wales	London
1941 .. ..	59	70	58
1942 .. ..	50	58	51
*1943 .. ..	49	51	49

\*Provisional.

Major MARKHAM also asked what was the infantile mortality rate for Scotland for 1943; and the latest comparable rates for Iceland, New Zealand, New York, and Chicago. Mr. JOHNSTON said that the infant mortality rate for Scotland for 1943 was 65 per 1,000 live births. The latest figures available for the other places were: New Zealand (1942, Europeans) 29; New York City (1940) 35; Chicago (1940) 29; Iceland (1936, rate calculated by U.S.A.) 48.

## Education Bill: Nursery Schools

Consideration of the Education Bill by the House of Commons in Committee was resumed on Feb. 15. On Clause 7, which deals with the stages and purposes of the statutory system of education, Mr. KEY moved an amendment which, he said, would rectify a grave omission in the Bill—the necessary arrangements for the children who at present attended nursery or infant schools. Under the Bill junior pupils were to comprise all children under 12, and nursery schools were regarded as being outside the normal provisions for children. They were excluded from the categories of county or auxiliary schools, and were specifically included in the special schools for mentally and physically defective children. There was very grave danger that those who had been hitherto regarded as infants in the separate establishments between the ages of 5 and 7 would find themselves merged into the general primary arrangements

# NICOTINAMIDE — SOME INDICATIONS

○ Nicotinamide (nicotinic acid amide) has exactly the same vitamin activity as nicotinic acid, but the flushing and tingling of the skin common with the acid do not occur when the amide is employed.

'Pelonin' Amide, brand of nicotinamide, is specific in pellagra, and in sub-pellagroid conditions manifested by such larval symptoms as indigestion,

irritability, burning of the skin, forgetfulness and insomnia. It is also used in glossitis, stomatitis, dermatitis, diarrhoea and mental disorders associated with nutritional defect. In psychotic disturbances of the aged, the debilitated, the arteriosclerotic and the chronic alcoholic, 'Pelonin' Amide often produces a favourable response.

PRODUCT OF THE  
GLAXO LABORATORIES

## "PELONIN" AMIDE

Brand of NICOTINAMIDE Ampoules and Tablets (50 mg. in each)

The vasodilatory action of nicotinic acid is itself sometimes desired, as in the treatment of certain vasospastic conditions, e.g., suitable cases of chilblains, Raynaud's disease, trigeminal neuralgia and Meniere's disease. For these, 'Pelonin' brand of nicotinic acid remains available.

GLAXO LABORATORIES LTD., GREENFORD, MIDDX. BYRON 3434

## Freely Flowing Bile Gathers No Stones

Veracolate is composed of the bile salts—sodium taurocholate and glycocholate—with a compound laxative to aid intestinal elimination. It is therefore indicated in all conditions where there is interference with the free flow of bile.

The range of conditions for which Veracolate is useful includes constipation, biliousness, flatulent dyspepsia, and catarrhal inflammation of the gall-bladder and its ducts.

Veracolate increases the production of bile, lowers its viscosity and relieves the symptoms associated with the gall-stone diathesis.

Veracolate keeps the bile flowing.

## VERACOLATE

TABLETS

Composition: Sodium Taurocholate and Sodium Glycocholate—with  
Cascara, Phenolphthalein and Capsicum

WILLIAM R. WARNER & CO., LTD., 150-158, KENSINGTON HIGH STREET, LONDON, W.8  
(Temporary Wartime Address)

# 'ASCABIOL'

TRADE MARK

brand of benzyl benzoate emulsion  
for the treatment of  
*scabies*

A single application of benzyl benzoate emulsion, provided it is thorough, will usually cure a case of scabies. The chief advantage of benzyl benzoate over some other sarcopticidal agents is the rarity of dermatitis following its use and recently the formula of 'Ascabiol' has been modified so that skin irritation following its use is minimal.

Recent clinical work indicates that this pre-

paration is effective also as a pediculicidal agent. A pamphlet describing life history of *Sarcoptes scabiei*, the properties of different sarcopticidal agents and the technique of the treatment of scabies will be sent on request. Pads of instruction cards for patients are also available. 'Ascabiol' brand of benzyl benzoate emulsion is supplied as follows:—

Bottles of 4 ozs. Bottles of 80 ozs.

## An obstinate case

Every Doctor sooner or later meets what appears to be a simple sore, or shallow ulcer, only to have the chagrin of finding it resistant to treatment, or obstinately slow in healing. This is frequently due to the presence of infection of low virulence, yet persistent in character.

**SULPHANILAMIDE TULLE (OPTREX BRAND)** is most successful in such cases, as abundant reports have amply confirmed.

**SULPHANILAMIDE TULLE (OPTREX BRAND)** is a wide mesh gauze dressing impregnated with an emulsion containing 10% sulphanilamide. It stimulates healing, is bacteriostatic, soothing, easy of application, allows drainage and does not stick to open sores, or cause pain or injury to fragile tissue on being removed.

The gauze of 2 m.m. mesh allows for adequate drainage. Two packings, both continuous strip, 5 yds. x 3½ ins. and 10 yds. x 2 ins.

A PRODUCT OF OPTREX LTD.

Full size Trial Tin will gladly be sent free of charge on receipt of signed order, as required under the Poisons Regulations, by:—

THE OLD MEDICAL SCHOOL, PARK STREET, LEEDS AND  
252 REGENT STREET, LONDON, W.1

and mixed with children from 7 to 11. The technique which had been worked out for dealing with the children in infants' day nursery schools had been a result of a scientific and psychological approach to child development. It would be a disastrous thing if the benefits of that were lost merely to get a merger of these two types of school. As soon as the attendance of the children over 5 was compulsory under the law, the one neglected, who would not receive the benefits of the nursery-school provision, would be the child under 5. The effect of trying to make small nursery schools near to homes would suit, almost inevitably, in an unqualified staff, and would cause a very harmful and unnecessary psychological break in the child's development. Dr. SUMMERSKILL, who supported the amendment, said it was difficult to understand why this system should have been divided into three stages—primary, secondary, and further education—and the preparatory stage absolutely neglected.

Mr. EDE said that this was a clause which tried to set out for the first time the conception that education was a continuous process. The Government believed that, where numbers made it possible, there should be a separate infants' department or children of compulsory school age under their seventh birthday. There must be elasticity in the system to allow any development from 5 to 7 to occur and so that their successors at some future date would be able to decide the appropriate age at which the preparatory stage should end.

The amendment was negatived.

The debate on the Bill was adjourned.

### Mass Radiography in Wales

On Feb. 15 Mr. JACKSON asked the Minister of Health how many extra beds had been allotted to meet the increased numbers of tuberculosis patients discovered by mass radiology in Wales, and if he was satisfied that the number was adequate. Mr. WILLINK said that it was not proposed that tuberculosis authorities should assign a quota of beds specifically to cases discovered through mass radiography. The proportion of persons examined by this method who were found to be tuberculous had to require institutional treatment was very small, and the mass radiography unit now operating in Wales should cause no substantial extra demand on sanatorium beds for some time to come. He was aware that tuberculosis accommodation in Wales and in other parts of the country fell short of what was desirable. Problems of building and staff were at present serious, but 240 additional beds for tuberculosis had been provided in Wales in the last eighteen months.

### Silicosis and Pneumoconiosis in Miners

On Feb. 15 Mr. J. GRIFFITHS asked the Minister of Fuel and Power how many miners have had to cease work at the mines in the past six months in consequence of being certified under the Silicosis and Pneumoconiosis Orders, and what steps were being taken to prevent the increase of this disease among miners. Major LLOYD GEORGE said that 819 workmen had been certified by the medical boards in the six months ended Dec. 31. It did not follow, however, that all these men had left the industry, and it would be necessary to make detailed inquiries to obtain precise details. He was aware of, and shared to the full, the concern felt about the increase in these numbers, but it was due almost entirely to the extension of the compensation scheme last July, which brought sufferers from pneumoconiosis within its scope. A number of expert committees, in addition to his own specialist inspectors, had the prevention of these diseases constantly under review, and on their advice he had made an Order conferring upon the inspectorate the power to require appliances to be installed for the suppression or extraction of air-borne dust below ground. This Order applied to South Wales, and came into operation on Jan. 1.

Mr. GRIFFITHS pointed out that in his own constituency 350 men were waiting to go before the board. He asked the Minister to increase the effort to combat this disease and, in particular, to see that what was being done was explained to the people concerned. Major LLOYD GEORGE replied that he would be very glad to do that. There was nobody more anxious than he to see every possible method of dealing with the disease used. He also promised Mr. Palmer to look into the question of the use of mass radiology.

Replying on Feb. 17 to questions by Mr. James Griffiths on the working of the Silicosis and Pneumoconiosis Orders, Mr. HERBERT MORRISON said that owing to the large increase in the number of applications to the medical board from South Wales miners examinations had been delayed. The strength of the medical board in South Wales had been doubled, and further assistance was being given so far as practicable. He recognized the desirability of doing everything possible to cope with the increased work, but claims on the medical profession at the present time made it difficult to secure the services of qualified men who could devote time to this work, and some

delay was unavoidable. As the result of discussions with representatives of the South Wales Miners' Federation he hoped that in future priority of application would be given to cases where the disease was advanced and the workman was incapacitated for work. The number of applications for certificates of disablement or suspension dealt with by the medical board under the Coal Mining Industry (Pneumoconiosis) Scheme, 1943, up to Feb. 5 was 1,285, of which 1,100 were in South Wales. The number certified to be totally disabled or suspended on account of the disease was 737, including 658 in South Wales. The numbers of applications from coal-miners dealt with by the medical board under the schemes of compensation and benefit under the Silicosis and Pneumoconiosis Orders for the year ended Dec. 31, 1943, was 2,645, of which 31 were from Lancashire and Cheshire. The number certified to be totally disabled or suspended on account of the disease was 1,281.

### Penicillin

Mr. CHARLES PEAT said on Feb. 16 that arrangements for the production of penicillin in Canada, the United States, and this country were co-ordinated by the Combined Production and Resources Board.

Major LYONS asked on Feb. 17 if the attention of the Minister of Health had been called to the production and use of home-made penicillin. Mr. WILLINK said that some research workers had published notes on so-called home-made penicillin. Small-scale production of this substance was attended by special difficulties of purification and standardization. He would certainly be glad to receive all information relative to the production and application of penicillin.

### Call-up of Doctors in Scotland

Sir EDMUND FINDLAY on Feb. 17 asked whether the Secretary for Scotland was aware that the Scottish Central Medical War Committee had sent calling-up notices to a number of doctors in the public health service, and whether the withdrawal of these doctors was justified on the grounds of national interest. Mr. JOHNSTON said the action of the Central Medical War Committee followed a recommendation by the Medical Personnel (Priority) Committee and was taken after careful local inquiry in the various local authority areas by his medical officers. He was reluctant to see any reduction in the Scottish public health services, but every effort had to be made to meet the urgent need for doctors to serve with the Forces. This might involve some temporary curtailment in the routine medical work of public health departments. He trusted that by co-operation with neighbouring authorities it would be possible to overtake essential public health duties.

## Medical News

Prof. B. A. McSwiney will deliver the Oliver-Sharpey Lectures before the Royal College of Physicians on Thursdays, March 2 and 9, at 4 p.m. His subject is "Afferent Fibres of the Abdominal Viscera."

A course of eight lectures on the physiology of the eye will be given at the Royal Eye Hospital, St. George's Circus, S.E., at 4.30 p.m. on Mondays, Feb. 28; March 6, 13, 20, and 27; April 17 and 24; and May 8, by Prof. Samson Wright and Dr. David Slome. These lectures are open to members of the medical profession and medical students.

The Ling Physical Education Association will hold refresher courses in (a) Leicester, on March 4, at the Newark Girls' Secondary School; (b) Bristol, on March 11, at the Red Maids' School, Westbury-on-Trym. At Leicester, Group Capt C. J. S. O'Malley will lecture on "Principles of Rehabilitation" at 11.15 a.m. Miss M. Forrester-Brown, M.S., will lecture on "Rest and Exercise in the School Curriculum."

Recently the Therapeutic Research Corporation of Great Britain, published a statement in regard to the mass production of penicillin. Lord Nuffield has been interested in penicillin since the discovery that the antibacterial properties of this extract of *Penicillium notatum* could be used for the cure of various bacterial diseases in human beings. At his suggestion the Nuffield Provincial Hospitals Trust early in 1943 undertook to make grants of £2,300 per annum for a period of five years towards the remuneration of the team of researchers working under Prof. Florey in Oxford. The University of Oxford accepted these grants from the Trust with gratitude. This action has been taken by the Trust with the concurrence of the Medical Research Council, which has been supporting the work for several years and is continuing to make a substantial grant for research expenses. Later, the Trust also agreed to make substantial grants towards the development of penicillin treatment of meningitis, brain abscess, and other pyogenic diseases of the central nervous system.

Specialists in the hospitals, higher salaries for nurses, and a new health education officer to supervise the teaching of hygiene in schools are among the items in Trinidad's health programme, on which £500,000 is to be spent this year. It is hoped that a start will be made on the island's £300,000 tuberculosis sanatorium. Two new health centres have already been built and the first rural dispensary is now being constructed. Three more health centres and eleven dispensaries are to follow. A child welfare centre established last year is proving very successful.

Queen Wilhelmina of the Netherlands has approved the appointment of Dr. J. E. Stanley Lee, M.B., F.R.C.S., F.R.F.P.S., of Wolverhampton to be an Officer in the Order of Orange-Nassau.

A grant of £28,600 has been made available under the Colonial Development and Welfare Act for a tuberculosis survey in Fiji. It is hoped to extend the survey to the British Solomon Islands Protectorate and the Gilbert and Ellice Islands Colony. The scheme will cover a preliminary survey only, mainly to determine the extent of the problem and the best means of dealing with it. A Government medical officer is undertaking preliminary work. A comprehensive scheme for the reorganization of the medical services of Fiji and the Western Pacific with assistance under the Act is contemplated, under which it is proposed to provide accommodation for 400 cases throughout the area.

The 50th anniversary of the foundation of the Johns Hopkins School of Medicine was observed on Oct. 2, 1943.

## EPIDEMIOLOGICAL NOTES

### Discussion of Table

In *England and Wales* notifications of measles rose by 243 and of scarlet fever by 104; those of diphtheria fell by 44.

The incidence of measles has mounted steadily during the past month, and the notifications are double the number at the beginning of the period. The only counties reporting a substantial rise during the week were Lancashire by 81, and London by 53, which together had 37% of the total notifications. There was a slight rise of scarlet fever throughout the country, but the only large local increase was Essex, with 43 more cases. The incidence of whooping-cough fell slightly in the north and rose slightly in the south, the balance yielding an increase of 12 for the whole country. After rising for five consecutive weeks the notifications of diphtheria fell by 44; there was a rise in Durham of 21, and a slight rise in the combined London and south-eastern region of 18.

With the exception of two areas, dysentery fell in incidence. The rises were in Surrey from 12 to 17, and Yorks West Riding from 10 to 27 (Aireborough U.D. 16). The other large returns were those of Lancashire 19, London 18, and Middlesex 17.

In *Scotland* scarlet fever went up by 24 cases, acute pneumonia by 17, diphtheria by 16, and whooping-cough by 10. The 41 more recorded notifications of dysentery were contributed, with the exception of 1 case, by 40 cases in Dunbarton County that occurred in January but had not been previously reported.

In *Eire* the notifications of diphtheria remained at a high level, and the incidence of measles rose by 52 cases: 199 of the 241 cases of measles were notified in Dublin C.B.

In *Northern Ireland* the notifications of scarlet fever went up by 20, with a total of 91 cases, 58 of which were reported from Belfast C.B.

### Vital Statistics of Scotland, 1943

The preliminary summary shows a birth rate of 18.9 per 1,000, 1.2 above the average of the five preceding years, and the rate was the highest since 1931. The infant mortality was 65 per 1,000 births and was the lowest rate ever recorded in Scotland, and 9 below the five-years average. Maternal mortality was 3.8 per 1,000 live births, 0.8 below the five-years average. The general death rate was 13.3 per 1,000, being 0.3 above the rate for 1942 but 0.2 below the five-years average. The death rate for all forms of tuberculosis was 79 per 100,000 and 59 for respiratory tuberculosis; these rates were respectively 1 and 2 below the rate for 1942, but 2 and 1 above the five-years average. The marriage rate was 7.6 per 1,000, which was a fall by 1.9 to the pre-war level.

### Week Ending February 12

The returns of infectious diseases in *England and Wales* during the week included: scarlet fever 1,870, whooping-cough 2,009, diphtheria 687, measles 1,245, acute pneumonia 909, cerebrospinal fever 62, dysentery 220, paratyphoid 5, typhoid 6. The deaths from influenza in the great towns numbered 51.

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 5.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

### ANY QUESTIONS?

#### Dyspepsia simulating Duodenal Ulcer

**Q.**—A woman aged 49 has for the last few years suffered from faint dyspepsia and epigastric pain two hours after meals, which is relieved by an alkaline powder. There is occasional tenderness over the appendix. There has been no loss of weight. The patient is constipated. Test meal shows a normal curve and the radiologist suspects duodenitis. What line of treatment should be followed?

**A.**—The case is probably an example of the comparatively common form of indigestion, possibly the result of duodenitis, which simulates duodenal ulcer, but in which there is no radiological confirmation of the diagnosis. The occasional tenderness over the appendix should not lead to its removal, which is more likely to do harm than good in the absence of evidence of recurrent subacute inflammation. The patient should be given the "post-ulcer regime"—the permanent routine for people who have had a duodenal ulcer which has healed under medical treatment.

1. A meal or feed (milk, plain biscuits, or chocolate) should be taken at intervals of not more than two hours from waking to retiring, and again if awake during the night.

2. The patient should eat slowly and chew very thoroughly. Adequate time should be allowed for meals, which must be punctual. She should avoid taking a meal when she is tired.

3. The patient should not smoke more than six cigarettes (or two pipes) a day, and these should be after meals. Cigarettes should have an absorbent plug in the mouthpiece.

4. During periods of overwork, and especially of mental stress, one day or half-day a week should be spent resting on a strict two-hourly diet. A sedative should be given if the patient is worried or sleeping badly.

5. If the patient gets a cold, sore throat, influenza, or other infection, bed-rest on a very light diet should be ordered until complete recovery.

6. Avoid alcohol, except (if desired) a small quantity of beer, light wine, or diluted whisky with (but never before) meals. Avoid pips and skins of fruit (raw, cooked, or in jam, and raisins, currants, figs, ginger, and lemon-pest in puddings and cakes), nuts, and unripe fruit. Avoid radishes and raw celery, tomato skins, stringy French beans, hard peas and beans. Coarse green vegetables must be passed through a colander. Avoid porridge made with coarse oatmeal, and rye. Avoid mustard, pepper, vinegar, curry, pickles, and chutney.

7. A teaspoonful of magnesium trisilicate should be taken an hour after meals and also whenever the slightest indigestion or heartburn is felt.

8. Isogel or liquid paraffin may be taken for the bowels if necessary, but no other aperient should be used.

9. No drugs in tablet form, no aspirin or vitamin, should be prescribed.

#### A Case of Rheumatic Fever?

**Q.**—A boy aged 18 has suffered from acute rheumatic fever for 12 months. He feels very well except that sometimes he has palpitations. His temperature persists in fluctuating between 99° F. and 98.2° F. in spite of salicylates gr. 20 given t.d.s. Should the salicylates given be increased, or should other treatment be adopted? He is, of course, still kept in bed.

**A.**—It is improbable that acute rheumatic fever has lasted for 12 months, especially in a boy who feels very well. Presumably there is no evidence of active carditis. The administration of salicylates solely for pyrexia is pointless and in this case ineffective. A prolonged course of 60 gr. daily may result in both palpitation and a low pyrexia. The first possibility to be envisaged is, however, the presence of focal sepsis such as often exists in the tonsils. If pyrexia is the only abnormal sign, salicylates should be stopped. If within a fortnight the temperature rises further and joint pains

appear the salicylate treatment should be reconstituted in doses of 20 gr. four times in the day and once in the night. Twice this quantity of sodium bicarbonate should be given concurrently. If, on the other hand, the pyrexia is unaffected or lowered by cessation of drug treatment the diagnosis of the present condition must be revised and the patient restored gradually to mobility.

#### Thiouracil for Hyperthyroidism

**Q.**—I would be glad of information concerning thiouracil, which I have heard is useful for thyrotoxicosis.

**A.**—Thiouracil is a fairly simple chemical substance which can be bought from the usual drug houses. It controls the symptoms of thyrotoxicosis, which are due to excessive production of thyroid hormone. Thiouracil given by mouth to patients prevents formation of thyroid hormone, though how it does so is unknown. The initial dose is usually 0.1 g. (or 1.5 gr.) given five times a day. After administration for 10 to 14 days the symptoms are greatly improved and the clinical picture changes. The heart rate and basal metabolic rate fall and the body weight goes up. The use of thiouracil must be controlled by determining the patient's basal metabolic rate every ten days, in order to determine the correct maintenance dose for each patient. After 3 weeks on the initial dosage it is usually necessary to reduce the dose to a daily total of 0.2 or 0.3 g. (3 to 4 gr.). Thiouracil occasionally produces a skin rash, but other toxic effects have not yet been described. Its administration can be continued for many months and possibly for many years.

#### Haemorrhage from Scalp Wounds

**Q.**—Most first-aid books teach the use of ring pads to control haemorrhage from scalp wounds with underlying fracture of the skull. Is their use recommended by authorities on head injuries? Are they being used in the present war for such cases?

**A.**—Ring pads are no longer used or recommended for the control of haemorrhage from a bleeding scalp. In an emergency the bleeding can be stopped by digital compression of the adjacent scalp on each side of the wound against the intact skull. The bleeding can also be stopped by haemostatic forceps, which are applied to the galea aponeurotica at intervals of 1 cm. and are then turned back over the skin edge. These can be left in position until the wound can be surgically cleaned and stitched up.

#### Intermenstrual Bleeding

**Q.**—A patient single, aged 32, has been troubled with her menses for years. She has the normal monthly period lasting six days approximately, and between each month has flow of lesser volume which lasts two to three days. Clinically she appears to be normal and I can find nothing wrong on vaginal examination. She looks well and is not anaemic, though she is easily tired while doing a full day's work. The condition is more of a worry than a great disability. Would treatment by hormone therapy help her, or do you class the case as physiological? Alternatively, vitamins A, D, and C have been suggested. What treatment, if any, do you suggest?

**A.**—This cyclical intermenstrual bleeding is almost certainly "ovulation haemorrhage." If so it should occur about the middle of a 28-day cycle. It is the result of a variation in the oestrogen production of the ovary during the change-over from the follicular to luteal phase, and is to be regarded as physiological and harmless. Its occurrence is the rule in the rhesus monkey and it is not uncommon in women—although the amount of bleeding is sometimes so slight that it passes unnoticed. The phenomenon should be explained to the patient and no treatment other than reassurance is required. If need be, however, the bleeding can be prevented by raising the oestrogen level of the blood over the period of ovulation. Stilboestrol 1 mg. t.d.s. by mouth or daily injections of 5 mg. oestradiol benzoate for two days before the anticipated onset of the bleeding should be sufficient. Injections of progesterone should be equally effective. It should be added that ovulation haemorrhage is likely to disappear spontaneously at any time.

#### The Varying Menstrual Cycle

**Q.**—With reference to your answer on the "safe period" on page 286 of the *Journal* of Aug. 28, 1943, and to menstrual periods of 21, 28, and 35 days, do these differing menstrual cycles correspond to different blood groups? The different blood groups are stated to correspond to different sizes of erythrocytes.

**A.**—There is no evidence to show that the length of the menstrual cycle is related to the blood group of an individual. The length of the cycle is determined by interaction between the anterior pituitary and the ovary. The pituitary gonadotrophins stimulate the ovary, whereas the ovarian hormones inhibit the pituitary; so once the cycle begins it proceeds automatically, although it can be influenced by nervous and other extraneous stimuli. So far as our knowledge goes at present the periodicity of menstruation is to be regarded as an inherent characteristic of an individual or as a manifestation of the individual's nervous and endocrine make-up. However, it is not an unchangeable feature, and is sometimes altered

after events such as the profound endocrine disturbance associated with pregnancy. It is therefore unlikely that the blood group, which is a constant factor, can have any bearing on menstrual periodicity.

#### Teaching Cleanliness to Infants

**Q.**—*At what age should an infant's training in cleanliness begin, how long should this take, and what are the successive steps, with due regard to modern psycho-analytic teaching? To what extent should discipline be used, and what form is recommended?*

**A.**—The subject has profound social implications, of which the questioner seems clearly aware. This answer, however, must be limited to practical points. It will be assumed that the question refers chiefly to sphincter control, and only secondarily to such matters as general cleanliness and tidiness.

Most children acquire spontaneous sphincter control at the latest by the time they are two years old. In a sense the problem is one dictated by our type of culture, which is intolerant of "dirt." The less anxiety and guilt about it is present in the adult's mind the more smoothly will unobtrusive cleanliness training proceed. It is a great convenience for the adult to begin "holding out" immediately after birth, as part of the general toilet after feeds. This appears to be accepted without opposition by the infant. It establishes a conditioned response the merits of which are its relation to the lenteric reflex and the saving of napkins. The chief point is that it must be done without fuss, not continued if the baby shows rebellion or distress, and failure should be taken with equanimity and without startled comment or emphasis.

The second stage comes often at nine months, when soiling and refusal to "oblige" seem to be part of the baby's healthy self-assertion. Here it is essential not to turn the situation into a battle of wills, and to avoid all fuss, anger however mild, or sorrow, despite the loss of the earlier "pseudo-control." It is probably wisest at this phase, which will pass, to adopt a *laissez-faire* attitude, and patiently, but not too promptly, restore the child to comfort. Smearing and playing with its faeces may occur and need occasion no alarm.

From twelve months onwards the discomforts on the one hand and pride and pleasure at production (magic word of our era!) on the other stimulate the child to excrete at the times when the pot is offered, especially if the adult shows, however unconsciously, her appreciation. The obvious delight in doing it at the wrong time must not be checked or connected in the child's mind with scolding or impatience. Later, after eighteen months, lapses will often cause spontaneous distress, and reassurance and an easy touch are required in handling. As mentioned, the problem usually ceases at this stage and may indeed resolve itself into the opposite one—retention and prolonged sessions. Occasional later relapses, up to five years or even later, usually at night or during illness or excitement, should be treated as of no significance.

In the matter of general urge of washing, etc., the widest differences are found. The average child very early comes to love its bath, which can be made the occasion of play and fun even for tiny babies. Pride and the ready imitation of adults rather than discipline and guilt should be the incentives to the much more resented face and hand washing of later childhood, which are also best incorporated in a routine, lapse from which is not made into an "incident." Clothing should be planned on the assumption that it is natural for little people to dirty them when they are busy. The pressure of civilization is so strong that in due time the normal child comes to conform to most of its canons.

Lastly, it may not be out of place to mention that sociological survey has shown the Japanese to impose the most rigorous excretory training on their infants. Need more be said?

#### Ptyalin in an Infant's Saliva

**Q.**—*We are told that ptyalin first appears in the saliva at about the eighth or ninth month—i.e., when the teeth begin to make the mastication and crushing of starch granules possible. Is this any indication for withholding starch from an infant's feeds until the teeth erupt? Is amylase present in the small intestine from birth, or does it make its appearance at the same time as ptyalin? How does the cooking of starch affect the matter?*

**A.**—Saliva plays very little part in the digestive processes of infants before the age of 6 months, but it is not true that ptyalin is absent from it until the age of 8 or 9 months. Saliva has slight starch-splitting power even at the age of 2 or 3 months. Amylopsin is present in the duodenum immediately after birth and before any food is given. Indeed Ibrahim showed that this enzyme was present in the pancreas of the six-months foetus. These facts and common experience suggest that there is no indication for withholding starch from an infant's food until the teeth erupt. Although it may not be desirable or necessary to put starch in a young infant's food, there is no doubt that it has the capacity to digest it from the earliest age. The cooking of starch renders it more easily digestible. Most of the proprietary starch foods have gone through a process of preliminary preparation or cooking which renders them more miscible and digestible.

#### Pin-hole Urinary Meatus

**Q.**—*Should an infant's pin-hole urinary meatus always be enlarged? I have not found an expression of views in textbooks consulted. In doing toddlers' clinics I find circumcision has been done and a pinhole meatus left untouched. The meatus tends to develop a scab obstructing urination and leading to dribbling. Does the meatus enlarge sufficiently with the passage of time, or with puberty?*

**A.**—A boy of 12 has been referred to me by his father for enuresis. He has a small though not quite pin-hole meatus; perhaps it is enlarging. His father says enuresis started at age 5, after pertussis, and the boy had hospital treatment (? belladonna extract) to age 11, without cure.

**A.**—As it has been established that an obstructed meatus in an infant may give rise to back-pressure effects upon the urinary system, it is advisable to pay attention to a pin-point meatus. The cause is the failure of proper canalization of the epithelial column from which the glans portion of the urethra is formed. Usually the passage of a moderate-sized probe on a few occasions is all that is necessary.

The problem of enuresis is a complicated one, about which agreement has not yet been reached. The psychological aspect at present claims most attention, but it is usually agreed that any physical abnormality, such as the question mentions, should be corrected, whatever other treatment may be adopted.

#### INCOME TAX

##### Debts collected Weekly

"INDUSTRIAL" asks as to the position of debts which have to be collected over long periods; must tax be paid on them before they are collected?

**A.**—Tax is due according to the amount of profits earned, whether received in cash or not. In many cases, however, practitioners make up their accounts on a "cash" basis, and the Revenue authorities have accepted this as an established custom, provided that the amount of the gross cash received can reasonably be assumed, taking one year with another, to be the same as the value of the debts put on the books. But once the "earnings" basis has been adopted the authorities are very reluctant to agree to a change to the legally incorrect but much more convenient "cash" basis.

#### LETTERS, NOTES, ETC.

##### Degeneration

Dr. C. G. GIBSON (Launceston) writes: Like the questioner in the first of "Any Questions?" in the *Journal* of Feb. 5 (p. 44) I am interested in, and thinking about, a disease which has been classed for many years among the "degenerations." He is interested in a case of "degeneration of the pyramidal tract"; I am interested in a case of "progressive muscular atrophy." For neither condition does there appear to be any treatment which can be described as curative. May this not in great measure depend on the fact that early investigators, in their attempts to arrange their ideas and to classify diseases according to the science of those days, were tempted, or forced, to use some such word as "degeneration," which ever afterwards seems to explain the cause of the condition, though the originator of the term knew quite well that it does nothing of the sort? In this inquisitive go-ahead age I think it would be an advance to give up the glib use of "degeneration" or "degenerative" in the nomenclature of diseases. "Degeneration" strikes me as resembling a dust-sheet put over something that has been shelved for future consideration.

##### Thumb-sucking and Tonsils and Adenoids

Dr. CHARLES BROOK (London, S.E.9) writes: I am informed that it is the practice of many medical officers at infant welfare centres to impress upon mothers the necessity for preventing their babies from sucking their thumbs, fingers, or fists, on the grounds that such a practice will cause enlarged tonsils and adenoids and irregular teeth. My experience with my own four children appears to contradict this theory entirely. The two who were suckers, not merely in infancy but up to the ages of 8 and 10, have never had enlarged tonsils or obstructive adenoids, and have perfectly regular teeth, while, on the other hand, the two non-suckers have had their tonsils and adenoids removed and one had to have corrective treatment for an irregular upper dentition. It would be interesting to learn whether other members of the medical profession with families have had a similar experience to the one that I have related.

##### Corrigendum

In the answer to the question on ergotamine tartrate for migraine, in the *Journal* of Feb. 12, p. 243, it was stated: "Ergotamine tartrate is now known to be useful for other forms of headache." "Now" should have been "not."

## CRANIAL-NERVE PALSIES WITH HERPES FOLLOWING GENERAL ANAESTHESIA

A REPORT FROM THE CENTRAL MIDDLESEX COUNTY HOSPITAL

COMPILED BY

J. H. HUMPHREY, M.B., B.Ch.\*

AND

MARGARET McCLELLAND, M.B., B.S., D.A.\*

During a period of four months 13 cases of cranial-nerve palsies following general anaesthesia have occurred at this hospital. The cases occurred in three small groups, with free intervals of four and nine weeks between. Two of the affected persons died, while the remainder are at various stages of recovery. The degree of severity varied from subjective trigeminal anaesthesia only to a complete picture of encephalitis, but the main features were remarkably constant and readily recognized. Twenty-four to forty-eight hours after use of a general anaesthetic the patient complained of a sense of coldness, numbness, or tightness round the lips, which in most cases during the course of the next two or three days had spread to involve the whole distribution of the fifth nerve on both sides. This subjective anaesthesia was usually associated with analgesia and anaesthesia over the same area, and in nearly every case there was difficulty in swallowing solid food owing to its "getting lost in the mouth." Three of the cases also showed motor fifth-nerve weakness. About the third post-operative day, in the majority, there appeared circumoral herpes of the febrile type. At this time, in those persons showing further involvement, affection of other cranial nerves became apparent—e.g., diplopia, facial weakness, palatal weakness, and tremor or deviation of the tongue. In those cases which showed improvement this began on the fifth to the tenth day, and the milder cases recovered rapidly (almost completely in a fortnight), whereas the severer cases still had residual subjective changes after five months. The herpes had disappeared by the end of ten days. On no occasion did we observe affection of the first, second (including rough testing of the visual fields), ninth, or eleventh nerve, but all the other cranial nerves were involved in one or more cases. Taste over the posterior one-third of the tongue was not tested, and the ninth nerve may have been involved. Only one patient had an extensor plantar response, and that was unilateral. None ran unduly high temperatures during the post-operative period. Six vomited more severely than we normally expect after operation, and five were noticeably depressed, listless, or confused for two or three days. Three only complained of severe headache. A typical history is that of Case 4.

### A Typical Case (No. 4)

A woman aged 25 was subjected to appendicectomy for acute appendicitis on July 30, 1943. Premedication was by morphine gr. 1/6 and hyoscine gr. 1/150. The anaesthetic employed was a combination of intravenous pentothal with cyclopropane and a little ether, given by closed circle with CO<sub>2</sub> absorption. The operation was a short one and the anaesthesia was without incident.

On Aug. 1 she complained that she had had a feeling of coldness of the face with double vision for 24 hours. At the same time there was some difficulty in opening and closing the mouth. On examination the left pupil was larger than the right. The reactions to light and accommodation were normal. There was double vision in all directions. The position of the false image indicated that the

diplopia was of third-nerve origin. There was no nystagmus and the fundi were normal. Hypo-algesia and hypo-aesthesia affected all the trigeminal field of each side. The corneal reflexes were diminished and the jaw-jerk was depressed. No muscular weakness affecting the fifth nerve could be detected. Subjectively the lips felt cold and the face numb and swollen. Food placed in the patient's mouth felt cold. There was bilateral facial weakness affecting the upper and lower face. No other abnormality could be detected in the cranial nerves. There was no neck rigidity or retraction.

The symptoms and signs remained unchanged until Aug. 2, when herpetic vesicles were found on the buccal mucous membrane on the left side of the mouth. These continued for three or four days. On Aug. 4 she complained of difficulty in swallowing. A lumbar puncture performed on the 6th yielded a clear fluid under normal pressure; no white cells were found. There was a gradual diminution in the cranial-nerve palsies; by Aug. 11 the difficulty in swallowing had disappeared, and by the 18th the diplopia had cleared. The scalp still felt abnormal. The skin over the forehead and the cheeks felt "swollen and stretched," and she complained of a peculiar tingling-sensation around the nose. The tongue and the teeth still felt cold and numb. The pupils were equal in size and the external ocular movements were full. Hypo-algesia and hypo-aesthesia were present over the whole distribution of the fifth nerve, but around the nose stimulation with a pin produced an exaggerated reaction. There was still left facial weakness. She was transferred for convalescence on Aug. 27.

The patient was seen again on Oct. 7. She stated that she had had transient diplopia, when tired, up to a week before her visit. The upper lip still felt "twice its size" and the eyelids and the forehead seemed heavy. Since her discharge on Aug. 27 she had noticed involuntary twitchings of both sides of the face, of very short duration. There was a slight degree of diminution of sensation to pin-prick on the right side of the face, affecting all divisions, with a slight left facial weakness. No other abnormality was found in the central nervous system.

Table 1 summarizes the clinical aspect of the cases. In it are included only those which showed definite cranial nerve involvement; but it should be mentioned that in association with them we encountered three cases of unexplained herpes developing about the third post-operative day, without complications other than severe headache or transient tingling of the lips. The clinical features require no further comment, except that involvement was usually (but not always) bilateral, and that in some the subjective fifth-nerve changes were accompanied by very definite changes in sensation to pin-prick, and light touch.

### History of Two Fatal Cases

Necropsies were performed upon the two fatal cases. Since Case 8 differed from all the others, a brief history is given.

#### Case 8

This patient was a woman aged 56. On Aug. 4, 1943, a cholecystectomy was performed, the anaesthesia lasting about one hour. She received premedication with morphine gr. 1/6 and atropine gr. 1/100, and anaesthesia (pentothal, nitrous oxide, oxygen, and ether) was maintained through a naso-tracheal tube by a closed-circle technique. The operation and anaesthesia were smooth and without incident. Post-operatively she was somewhat slow in returning to consciousness, and vomited rather more than is usual. Next

\* Other members of the staff contributing to the work were T. G. I. James, M.S., F.R.C.S.; H. Joules, M.D., F.R.C.P.; Miss S. Ransom, M.R.C.S., L.R.C.P., D.A.; W. Pagel, M.D.; and E. D. van der Walt, M.R.C.P.

day she was apathetic, and in the evening she became delirious, with twitching round the mouth during the night.

On the following day she was ill and confused. Her left pupil was larger than the right, and was fixed and inactive to light. There was bilateral fifth-nerve analgesia with absent corneal and conjunctival reflexes. She had a gross tremor of the tongue, and marked incoordination of the arms, which was worse on the right than on the left. Her condition gradually deteriorated, and bilateral facial

enlarged prostate, bronchopneumonia, and some general oedema of the brain.

**Histology.**—Occasional small capillary haemorrhages were seen in sections through the pons and midbrain, together with small perivascular collections of lymphocytes in the substantia nigra. In addition to the lymphocytic cuffing, macrophages containing haemosiderin were found in sections through the cerebellum. The upper part of the medulla oblongata contained occasional collections of

TABLE I.—*Clinical Summary of Cases*

No.	Sex	Age	Operation Date	Nature of Operation	Anaesthetic	Duration of Anaesthesia	Post-op. Vomiting	Herpes	Cranial Nerves Involved	Comment

13	F	35	27/10/43	Evacuation of uterus: severe blood loss	"	5 "	—	+	L. V, "transient" L. VII	Followed Case 12 on table

Pent.=pentothal. Cyclo.=cyclopropane. Gas=nitrous oxide. O<sub>2</sub>=oxygen. Trileoe=trichloroethylene.

weakness became apparent. During the afternoon she became stuporous, with jerking movements of the legs and arms. Lumbar puncture yielded 3 c.cm. of clear faintly yellow fluid under normal pressure: protein, 1.70 g. per 100 c.cm.; 14 polymorphs per c.mm. She died in coma at 10 p.m. on Aug. 6.

Necropsy was performed by Dr. W. Pagel 12 hours later: "The operation wound was sound. There was no gross abnormality of any organ except the brain, which showed marked oedema. Cultures of c.s.f. were sterile, and there was no meningitis."

**Histology** (Dr. Pagel).—There was no evidence of fat embolism anywhere in the parts examined. In all sections through the mid-brain and the floor of the fourth ventricle there was marked deposition of thready material in the perivascular lymph spaces (oedema). There were seen in addition a few vessels surrounded by a single row of lymphocytes, and a few capillary haemorrhages into the perivascular lymph spaces, together with collections of microglia in the neighbourhood of vessels. The ganglion cells in the central grey matter and the medulla oblongata were free from appreciable changes.

**Summary of Case.**—Marked oedema in the midbrain, pons, and medulla oblongata. Small capillary haemorrhages and beginning slight cuffing around the vessels. No changes in the ganglion cells. Portions of brain from the region of the affected nuclei were removed for animal inoculation.

#### Case 11

This patient, a man aged 74, was suffering from retention of urine due to an enlarged prostate (blood urine, 168 mg. per 100 c.cm.) and from chronic bronchitis with emphysema. He had auricular fibrillation, which was controlled by digitalis. A cystoscopic examination was made and suprapubic cystostomy performed under cyclopropane and oxygen anaesthesia, after premedication with morphine gr. 1/6 and atropine gr. 1/100. The anaesthesia lasted about three-quarters of an hour. Post-operative cranial-nerve involvement was extensive but not severe, and included the fifth nerve: subjective numbness in all divisions, with hypo-algesia and pins-and-needles sensation over the nose. His jaw deviated to the left. The palatal reflex was absent, although palate movement was normal. The sixth nerve showed slight left external rectus weakness, and the seventh nerve slight bilateral lower facial weakness. His chief difficulty lay in an inability to swallow solids, though he had no nasal regurgitation. Although suprapubic drainage was adequate he went progressively downhill. He was quite unable to swallow fluids towards the end, and died on the sixteenth post-operative day. At the necropsy, performed by Dr. Pagel, the only findings of significance were an

microglia in star formations. Oedema was also present, but was much less intense than in Case 8. The small haemorrhages might be due to terminal respiratory embarrassment. In photomicrograph taken of sections from the two brains the most noticeable feature in each case was probably the oedema of brain and brain-stem, although there was no clear histological evidence of the cause of the condition.

**Other Pathological Findings.**—Lumbar puncture was performed upon nine of the patients during the first week. The pressure was never raised, and in all cases the cerebrospinal fluid was bacteriologically sterile. In only two cases was there a small increase of polymorphs (10 and 14 per c.mm.). In four the protein content was 0.04% or less, while the remainder contained 0.055%, 0.07%, 0.085%, 0.09%, and 1.7%.

**Animal Inoculation.**—We were fortunate in obtaining the help of Dr. C. H. Andrewes, of the National Institute for Medical Research, who performed many of the inoculations. Cerebrospinal fluid from five cases and portions of brain removed at necropsy from two cases (some glycerinated, some filtered through a 0.7  $\mu$  membrane and held at  $-70^{\circ}$  C.) were injected intracerebrally or intratesterically into a total of 44 mice, 1 rabbits, and 1 rhesus monkey. No evidence of transfer of virus infection was obtained.

#### Theories of Aetiology

The cases described were operated upon by four different surgeons and anaesthetized by three different anaesthetists. None of them showed signs of anoxaemia or other complication upon the table. There was no evidence to incriminate any definite ward, but it was notable that all the anaesthetics were given in one theatre and all on the same type of machine. It seemed to us that the damage must have been directly due to the anaesthetic or to the lighting up of some latent virus infection, or both. The mode of anaesthesia and certain serological findings are presented with these possibilities in mind.

#### Anaesthetics

It will be observed from Table I that the anaesthetics were variable and that no one drug was common to all cases. The major surgery of the hospital is done in two operating theatres. The anaesthetic machine used in 12 of the 13 cases is one with which either a simple semi-open "to-and-fro" method may be used or else a closed-circle technique, with a soda-lime

canister incorporated to absorb the carbon dioxide. There is only one bottle on the machine. It contains a gauze wick. This wick retains a little of whatever anaesthetic drug has been in the bottle previously, and thereby contaminates the drug next used—e.g., ether following trichloroethylene, or vice versa (see accompanying diagram).

Although a number of tests had shown the bag and corrugated rubber tubing of the machine to be free of viable bacteria when swabbed immediately after use, this machine was sent to be sterilized in August. While it was away the same type of circle absorber was attached to a Boyle apparatus, and on this one case of palsy occurred (No. 9). In the other theatre a simple Boyle apparatus without soda-lime absorber is used, and on this there were no cases.

The anaesthetics administered were varied, but all except two were well-tried mixtures—namely, Cases 1 and 9, which received pentothal followed by cyclopropane and trichloroethylene, using the closed-circle technique. Ether, pentothal, and cyclopropane are drugs which have been used very extensively and have withstood the tests of time and experience. Trichloroethylene has been more recently introduced into anaesthetic practice, and has only been widely used in England since Hewer's report of 400 administrations and review of experimental work on animals (Hewer, 1942), although, in America, Striker and his colleagues were using it in 1935. Two reports of fifth-nerve palsy following the administration of trichloroethylene anaesthetics appeared during the past year (Hewer, 1943; McAuley, 1943). In the cases reported by Hewer impurities in the drug were considered to be the cause. Earlier reports in the German literature record cases of trigeminal palsy developing in industrial workers using trichloroethylene, toxic contaminants being regarded as a possible cause (Stüber, 1931; Jackson, 1934). Therefore, although this drug was used upon only two of our cases it was naturally suspect.

During the four months July to October 940 inhalation anaesthetics were administered in the two theatres, of which 600 were given in Theatre I (where all the cases occurred) and 340 in Theatre II. Each main drug, associated with others, was used in the following proportion of cases: ether 35%, cyclopropane 24%, trichloroethylene 16%, and pentothal 25%. Nitrous oxide was used in many and oxygen in all. On the circle machine in Theatre I there were 80 administrations of trichloroethylene, and on the Boyle apparatus in Theatre II there were 65.

These figures appear to give very little clue to the problem, but the occurrence of all the cases on the circle machine led us to suspect that a possible toxic agent might result from the interaction of traces of trichloroethylene with soda-lime or the other drugs used. It has been pointed out (Morton, 1943; Stüber, 1931) that chemical reactions may occur between trichloroethylene and alkalis, particularly when heated. Owing to its low volatility trichloroethylene is not regularly used on a closed circuit, but during the period under review this was done on several occasions (including Cases 1 and 9). It is also conceivable that in our anaesthetic machine (described above) trichloroethylene used by the "to-and-fro" technique might linger in the machine or in the gauze wick, and thus be carried over into the soda-lime when a subsequent anaesthetic was given by closed circuit. In either case there would be definite possibilities of chemical reactions occurring, especially since we have noted temperatures of the order of

70° C. in the soda-lime canister. Our suspicion was strengthened by the presence of an unusual sweetish penetrating odour frequently noted about the machine during this period. (The odour was subsequently reproduced by incubating trichloroethylene with soda-lime.)

Dr. H. E. Cox, D.Sc., F.I.C., undertook to analyse the drugs used, paying particular attention to possible chemical reactions or impurities. A summary of his report is as follows:

(1) The cyclopropane, ether, and trichloroethylene fulfilled the prescribed conditions of purity. (2) There is no evidence of any change, under the conditions of administration, in (a) cyclopropane or (b) ether which would cause injury. (3) There is evidence of reaction between trichloroethylene and soda-lime, and (4) this reaction produces dichloroacetylene. This substance readily combines with oxygen to form phosgene, carbon monoxide, and carbon dioxide, but does not further oxidize in the presence of sufficient excess of trichloroethylene. (5) The reaction is greatly stimulated by rise of temperature in the soda-lime; it proceeds markedly even at blood heat. (6) There is no evidence of direct formation of oxidation products in the trichloroethylene without soda-lime. (7) The effects of dichloroacetylene in trichloroethylene are not known, but should be ascertained. (Dichloroacetylene is a substance explosive in the presence of limited oxygen.)

Experiments are at present being undertaken to find out the physiological effects of the reaction products of trichloroethylene and soda-lime. Dr. Cox's observations have been confirmed by the Department for Research in Industrial Medicine of the Medical Research Council, which is meanwhile making investigations of the toxicity of these substances to rats. We ourselves have obtained some striking preliminary results with rabbits. The animals were subjected to anaesthetic mixtures consisting of trichloroethylene plus 0.5–1.0% dichloroacetylene or of ether plus trichloroethylene plus 0.5–1.0% dichloroacetylene given in the same way, and on the same anaesthetic machine as was used for the cases under review. Each animal received the mixture under test for three periods of about 20 minutes at five-day intervals. Anaesthesia was light, and difficult to maintain when ether was not used, and the rabbits appeared to recover quickly and to show no untoward symptoms. After the third anaesthesia one rabbit was killed by an overdose of anaesthetic, and the other was killed seven days later by stunning. Histology of both was very similar, and showed little change in any organ except the brain and the liver, in which there was slight necrosis. In the brain there was extremely marked perivascular cuffing and glial proliferation throughout, with numerous foci of necrosis. There was even a marked meningeal reaction, and the picture at first sight was one of encephalitis. We have never met such a histological picture in any other of our rabbit stock, and, although further work is necessary, have no hesitation in attributing it to the anaesthetic. On the strength of this preliminary evidence it would appear advisable not to use trichloroethylene in the presence of soda-lime.

#### Temperature

It is well known that when artificial hyperthermia is induced in normal persons a high proportion (about 70%) develop labial herpes 2 to 3 days later (Keddie, Rees, and Epstein, 1941). A combination of anaesthesia with overheating of the patient by heat generated in the soda-lime might have provided a possible explanation for the herpes, the palsies, and the peculiar incidence. In a number of cases the temperature in the rubber tubing leading to the patient was recorded, the maximum reached being only a few degrees above room temperature. The axillary temperatures of the patients rarely varied more than  $\pm 1^\circ$  F. during operation. Although none of these patients developed symptoms there was no evidence to support this idea as a possible explanation.

#### Virus Infection

The occurrence of herpes on the third day in nine out of the twelve patients who survived this period was particularly striking in view of the fact that none of them had colds or any other condition commonly associated with herpes, and that half of them after careful questioning denied ever having previously had this condition. Among other operation cases the incidence at that time, in the absence of colds, was very low.

The lesions were characteristic of herpes febrilis, consisting of numerous discrete vesicles upon the mucocutaneous junction of the lips, the chin, and occasionally the buccal mucous

membrane and soft palate. In four cases successful transfer to rabbits was obtained by intracorneal inoculation of vesicle fluid, and the strains behaved typically. One strain (Case 10) was studied particularly by Dr. C. H. Andrewes and ourselves, and was adapted to rabbit testicle and skin, to guinea-pig pads, and to mouse brain. None of the strains was particularly neurotropic in rabbits or guinea-pigs, although direct intracerebral inoculation in a rabbit produced death from encephalitis after some weeks.

Herpetic encephalitis in man has never been authenticated, although during the epidemic of encephalitis lethargica in Europe after the last war numerous attempts were made to incriminate the virus, and its isolation was claimed from the brains of the affected and of normal persons (Doerr and Berger, 1922; Flexner and Amoss, 1925). Studies by Andrewes and Carmichael (1930) and by Brain (1932) showed that 70 to 75% of hospital patients have antibodies to herpes in their blood. In the majority of such persons overt lesions can be produced by artificial hyperthermia, intravenous T.A.B. vaccine, lobar pneumonia, meningococcal meningitis, the common cold, etc. Herpes occurs occasionally after injection of the Gasserian ganglion (Harris, 1937).

All the cases showed a definite incubation period between operation and the first appearance of symptoms, ranging from 24 hours to three days. This is very short, by accepted standards, for a virus infection. The post-mortem findings, on the other hand, were not inconsistent with an encephalitis, and were comparable with descriptions of some of the findings in the encephalitis lethargica epidemic. In the absence of a completely satisfactory "toxic" explanation, it was considered worth while to investigate the sera of these patients for antibodies against the herpes strain from Case 10 and another strain isolated at the National Institute for Medical Research by Dr. Andrewes. The viruses were adapted to the rabbit's skin, and each serum was tested for its power to inhibit the production of lesions by 5 to 10 infective doses of virus injected intracutaneously. The results are given in Table II.

TABLE II.—Results of Tests for Antibodies against Herpes

Case No.	Herpes	Herpetic History	Time of taking Serum after Operation	Neutralizing Antibodies	
				Strain 10	M.R.C. Strain
1	—	—	13 weeks	+	+
2	+	—	19 "	+	+
3	+	—	6 "	+	+
4	+	—	4 days	+	+
5	+	—	3 "	+	+
6	+	+	Not done		
7	—	—	7 days	+	+
8	—	?	2 "	+	+
9	+	—	11 "	+	+
10	+	+	6 weeks	+	+
11	—	—	4 days	+	+
12	+	+	1 day	+	+
13	+	+	1 "	+	+

It is evident that every serum contains antibodies against both strains. The most significant samples are the early ones from patients without herpetic histories, since in these cases the formation of antibodies would have been too rapid to be due to the herpes occurring at that time, quite apart from the fact that some never developed the condition. Herpes antibodies are commonly found in persons with latent infection, and the implication is that all these patients had latent herpes.

We were not able to demonstrate any immunological difference between the two strains by cross-protection tests, and cannot claim unusual virulence for the strain 10 studied. If herpes or any other virus infection is involved it must have been "lit up" by the anaesthetic. There is some experimental evidence for this possibility in the observation of Fiala (1943) that subdural or intravenous injection of vaccinia virus in rabbits is not normally followed by encephalitis, but is so if the rabbits are under urethane anaesthesia; or the work of Silberstein and Hoff (1925), who showed that a normally latent encephalitis virus could be activated in dogs with an Eck fistula by feeding with a diet of meat only. Argument by analogy is dangerous, however, and in the absence of positive findings from the inoculation of post-mortem material into susceptible animals we are unwilling to do more than suggest the possibility that herpes virus played a part.

## Discussion

The clinical evidence favours two possible theories, or a combination of both, but the experimental results are strongly in favour of a toxic theory. If the latter is adopted there must have been great susceptibility, since one anaesthesia (Case 13) was of five minutes' duration and the patient developed well marked palsy.

The only drug which could be incriminated is trichloroethylene plus soda-lime, and this only on the assumption that it could have persisted in the machine or in the soda-lime between the anaesthesias in which it was used. On two occasions as long as three days elapsed between the use of trichloroethylene and the anaesthetic which was followed by palsies, and during the intervals there had been given nine and twelve closed-circuit cyclopropane or ether anaesthesias respectively on the same machine without any ill effects. On another occasion trichloroethylene was followed on three succeeding days by varied anaesthetics which developed palsies. Four closed circuits, but no further trichloroethylene, had meanwhile been administered. Seven only of the cases were associated with the use of trichloroethylene on the same day, and of these two actually received the drug in closed circuit. It should be mentioned that the soda-lime was periodically "rested" for any time up to two or three days, and the use of contaminated soda-lime at a later date might explain the intervals between trichloroethylene administration and the anaesthesias which were followed by palsies. We consider it to have been a definite possibility that the majority of the patients who were anaesthetized on the circle machine were subjected to this risk. The fact that only a small proportion showed symptoms would mean that there must be great variation in susceptibility. Such variations are well known in toxicology.

The first case of the series was missed until 4½ months later when a chance remark of the patient's drew attention to his lesion. It seems to us possible that mild cases may have occurred elsewhere, and the facts recorded above have been published in the hope that the observations of others may help to shed light upon the problem.

It is now over three months since we ceased using trichloroethylene in association with soda-lime, and although many trichloroethylene anaesthesias, some lasting up to three hours have been given, no further palsies have occurred.

## Summary

Thirteen cases of cranial-nerve palsy following general anaesthesia are reported. The nerves involved were mainly the fifth and seventh, but the third, fourth, sixth, tenth, and twelfth were involved in some cases. The condition was associated with labial herpes in 9 cases.

No anaesthetic drug was common to all cases, but all were administered on a circle absorber anaesthetic machine.

Evidence is given for chemical reactions between soda-lime and trichloroethylene in the system, with the production of dichloroacetylene.

Preliminary results show that this substance is toxic to rabbits.

Antibodies against herpes were found in the sera of all cases.

The aetiology of the condition is discussed. It is concluded that until further investigations have been made trichloroethylene should not be used where there is any possibility of its coming into contact with soda-lime.

Our thanks are due to Dr. C. H. Andrewes, Dr. Donald Hunter, Dr. C. L. Hewer, Dr. J. G. Greenfield, and Dr. H. E. Cox for much help and advice.

## HAZARDS IN THE USE OF THE CLOSED-CIRCUIT TECHNIQUE FOR TRILENE ANAESTHESIA

BY

S. CARDEN, M.B., D.A., D.P.M.

Within the past two years trilene (trichloroethylene) has been increasingly used as a form of general anaesthesia. It has certain advantages over ether and cyclopropane, such as non-inflammability, and it is regarded as safer than chloroform, for there is much less risk of ventricular fibrillation. When diathermy is necessary, particularly in the region of the head and neck, trilene commends itself as a suitable non-explosive anaesthetic agent. As a rule I have limited my use of trilene to thyroid and breast operation cases. Its use in a closed-circuit machine appears to fall in line with what is almost a routine practice of most anaesthetists—that is, the carbon dioxide absorption technique for inhalational anaesthetics. There are many advantages of such a method, the outstanding one being that a quiet operation field is ensured by the diminished respiratory excursions. In cyclopropane anaesthesia this technique is of course essential for practical and economic considerations. The purpose of this paper is to show that it is dangerous to use trilene with a closed-circuit technique.

### Illustrative Cases

**Case 1.**—Mrs. A., aged 67, a frail thin woman, was a poor risk for operation for stone in the hepatic duct. On Nov. 22, 1943, she was given premedication of omopon gr. 1/6 and scopolamine gr. 1/300; then pentothal g. 0.5, followed by endotracheal cyclopropane. The operation lasted 1½ hours, during which she was given 750 c.c. of plasma. No trilene was used in this case. The same apparatus, however, had been employed to administer trilene to a patient immediately preceding this one. In the evening following operation her temperature was 99° F. and she vomited repeatedly. This vomiting started 12 hours after operation and continued for three days, when she first complained of difficulty in swallowing and numbness over the face. She was seen by Dr. Wilfred Harris on Dec. 11, and I am indebted to him for the following neurological notes: "Slight diplopia in all directions. Left third nerve shows partial palsy, and the left pupil is sluggish. There is bilateral slight weakness of both external recti, with homonymous diplopia. The voice is markedly nasal and there has been nasal regurgitation, and the right soft palate is obviously paretic. Fifth nerve:—There is total anaesthesia to pin-prick and even hand pressure over both first divisions, and the right second division, including the hard palate. The left second division is totally analgesic to pin-prick, but hand pressure is felt on the cheek. Moderate analgesia of third division on both sides, mostly on the right. Total motor palsy, with complete jaw-drop, is present. There is loss to taste over the right second division on the palate, but taste on both sides of tongue is fair."

This patient had to have a gastrostomy (under local anaesthesia) on Dec. 26 because of the inability to swallow. The gastrostomy tube was removed after five weeks (Jan. 31, 1944), and she is now swallowing food reasonably well. Although her general condition has vastly improved, the fifth and other nerve palsies show slight improvement only.

**Case 2.**—Miss B., aged 50; operation, Dec. 6, 1943—local excision of benign tumour of breast. Premedication, omopon gr. 1/3, scopolamine gr. 1/150, pentothal g. 0.5 in bed were followed by a very short further induction with cyclopropane and by nitrous oxide, oxygen, and trilene, using the closed-circuit technique. The duration was only 20 minutes. About 12 hours after the operation vomiting started; this continued for 36 hours. On the evening of Dec. 7 the temperature was 99°, and lasted two days. In the early morning of Dec. 8 she complained of double vision, stiffness of the face, and difficulty in swallowing. Dr. Harris saw her on Dec. 11, and reported: "She has a bilateral third-nerve paresis, the right being practically complete. The right pupil is much dilated, with very little reaction to light or convergence. Fifth nerve:—She complains that the face feels hot and 'tingly' over both cheeks (second division). Nearly complete analgesia to pin-prick over first and second divisions of both sides, including conjunctivae, and upper gums and palate. No pain on pricking the inside of nostrils. No motor fifth-nerve weakness, the masseters and external pterygoids being strong. Little if any anaesthesia of the third division of fifth. Sense of smell good. She has no nasal regurgitation, the soft palate rises normally on phonation, and there is no analgesia of the pharynx; but there is a suggestion of slight palatal weakness, because she cannot blow out her cheeks properly." There has been only

very slight improvement in this patient eight weeks after the onset of the paralysis.

Both cases therefore showed well-marked bilateral trigeminal anaesthesia, oculomotor palsy, and also difficulty in swallowing, the latter symptom being more pronounced in Case 1.

In the first case the trigeminal paralysis was total for the upper two divisions, with a total motor fifth-nerve palsy. In this first case, too, the right half of the soft palate was completely paralysed (tenth cranial nerve), and though the oculomotor paralysis was less than in Case 2 there was additional weakness of both sixth nerves. Case 1 also showed scars of recent herpes on the right upper and lower lips, which strongly suggest that a "toxin" had affected the Gasserian ganglion. Dr. Harris pointed out that herpes frequently appears over the lips and nares after Gasserian alcohol injections.

### Discussion

On making inquiries it was found that a case immediately preceding Case 1, on Nov. 22, had pentothal, nitrous oxide, oxygen, and trilene, via a closed-circuit machine, for the removal of an adenoma of the thyroid; this patient subsequently vomited a good deal and complained of giddiness. She was seen a few weeks later, but there was no evidence of her having had any paralysis. It is worth emphasizing that Case 1 did not have trilene, and it should be noted—an important fact—that the soda-lime canister was not changed between the cases. Case 1 would thus have been exposed to a prolonged inhalation of any toxic products that may have formed in the soda-lime canister when the trilene had been administered to the immediately previous case. The idea that a toxic product had formed in that canister was suggested by the fact that between the dates of the first case (Nov. 22) and the second (Dec. 6) eight others were given pentothal followed by cyclopropane anaesthesia with the same apparatus, and with no ensuing paralysis. It seemed an extraordinary coincidence that on the only two days that trilene was used a patient developed paralysis. Also it was noted that only recently at this hospital, for the convenience of dispensary ordering, a change-over had been made to another well-known brand of soda-lime (B). This appeared to give very good absorption clinically; but it was noticed that the canister became much hotter than with the previous brand, A (sodalime soda-lime). Another point with Brand B was that when it was necessary to change the soda-lime it was often found to be caked, and sometimes had to be dug out of the canister; whereas Brand A could always be easily shaken out. This led to the conclusion that Brand B, though it gave very good absorption, was the more hygroscopic. Accordingly, a full investigation, and analyses, of the soda-lime, trilene, and cyclopropane were started, and Dr. H. E. Cox kindly undertook the chemical analyses. Results of analyses of the two brands were:

	A (Sodalime)	B
Calcium hydroxide .. ..	84.1%	77.6%
Sodium hydroxide .. ..	1.2%	11.2%
Carbonate (calculated as Na <sub>2</sub> CO <sub>3</sub> ) ..	4.8%	5.4%
Moisture .. ..	7.4%	3.0%

Equal quantities of the two were then exposed in a moist atmosphere at room temperature, showing:

	A	B
Water absorbed after 18 hours ..	0.54%	2.23%
" " " 66 " ..	1.35%	6.77%

It will be observed that the clinical finding that Brand B has a greater avidity for water is confirmed. Also, it is particularly important to note that the caustic soda content of B is more than 9 times that of A. The significance of the latter point is discussed shortly. In his analysis Dr. Cox found no evidence of any deleterious substances in the cyclopropane or trilene; but experiment showed that, whereas when cyclopropane was passed through soda-lime no reaction occurred, with trilene through soda-lime a reaction took place, producing a distinctive sour smell. This reaction took place slowly at room temperature and rapidly at blood heat. As I have personally recorded temperatures of 110° F. using Brand A soda-lime and 178° F. when using Brand B in the canister of a circle absorber under conditions of anaesthesia, it will be readily understood that any chemical interaction will almost certainly be considerably speeded by this increased warmth. Trilene is itself very reactive, and is a derivative of acetylene, which chemically is one of the most reactive compounds

known. Dr. Cox also pointed out that trilene with soda-lime produces new and potentially toxic products, one of which is dichloroacetylene. This is easily oxidized to phosgene and carbon monoxide.

Trilene heated with alkali produces dichloroacetylene, and experiment shows a recognizable formation of this at even 98° F. If the heating is continued in the open, the dichloroacetylene, being very volatile, disappears, but if a condenser is used the dichloroacetylene accumulates and there is an explosion, producing phosgene. But when an excess of trilene vapour or an inert gas is maintained, dichloroacetylene does not further oxidize, and no explosion or phosgene formation occurs. This explains the fact that experimentally no phosgene reaction occurred in the circuit of the apparatus. The distinctive smell noted above is almost certainly due to the formation of dichloroacetylene, the physiological activity of which is at the present time unknown, and it is dismissed in all the literature as spontaneously explosive.

The fact that Brand B soda-lime is shown to contain more than nine times the amount of caustic soda, that it is more hygroscopic, and that it generates more heat under anaesthesia supports the clinical observation that this brand would definitely be more reactive towards trilene, with the production of toxic oxidation substances. This view is supported by the clinical evidence that no case of paralysis occurred while Brand A of soda-lime was used at the hospital; and no case occurred when employing my own apparatus for closed-circuit trilene anaesthesia, in which Brand A has always been used. The high temperature generated by Brand B soda-lime, and therefore of the inhaled anaesthetic gases, is of further disadvantage to the patient; it leads to excessive sweating and capillary engorgement (Hewer, 1942) even at 104° F.

### Conclusion

The relatively low incidence of post-trilene paralysis is, according to the above facts, due to three factors:

1. Fortunately, the vast majority of administrations with this anaesthetic agent have been given in an open circuit. As there is no evidence of direct formation of oxidation products in the trilene without soda-lime, it seems that there is no apparent risk when trilene is used in an open circuit.

2. The high temperatures generated and recorded in the canister of a circle absorber during anaesthesia have been at the point of maximum intensity of reaction, usually after the soda-lime has been in use for about an hour. If the soda-lime has already been in use for some time we do not get these very high temperatures, which are an exciting factor in the oxidation of the trilene into toxic products.

3. The actual amount of caustic soda available for this chemical reaction with the trilene has been shown to be considerably higher in some brands of soda-lime. It appears to be the most important factor—apart from the rise in temperature—for this effect on the trilene.

McAuley (1943) describes three cases of bilateral trigeminal anaesthesia, and it is to be noted that in every case the closed-circuit technique had been used. Lengthy anaesthesia does not seem to be necessary for full toxic effect. In his cases the durations were 20 minutes, 30 minutes, and 1½ hours, and in one of my cases the anaesthesia lasted only 20 minutes.

### Summary

Evidence is brought that trilene anaesthesia in a closed circuit is dangerous, and may result in trigeminal and other cranial-nerve palsies. The palsies are disabling and may be permanent.

This danger is shown to be due to toxic oxidation products formed by the interaction of soda-lime and trilene.

This reaction is speeded by the heat generated in the soda-lime.

The exact caustic soda content and hygroscopic properties are shown to vary in different brands. This, it is indicated, is an important factor in the occurrence of these cases.

My grateful thanks are due to Dr. H. E. Cox for his help in these investigations. I also wish to thank Mr. Lancelot Bromley for much encouragement and for many helpful discussions.

## INTELLIGENCE AND SEASON OF CONCEPTION

BY

J. A. FRASER ROBERTS, M.D., D.Sc.  
M.R.C.P., F.R.S.Ed.

Director, Burden Mental Research Department, Stoke Park Colony  
Bristol; Temp. Surg. Cmdr., R.N.V.R.; Consultant in Medical  
Statistics, Royal Navy

Many studies have shown that there is an association between season of birth, or of conception, and intelligence. The evidence has recently been ably marshalled by Fitt (1941) himself the contributor of the most substantial body of data. Children whose time of conception is centred on the winter months are on the average somewhat more intelligent than those conceived during the other half of the year. After analysing the results of the various investigations, which naturally show a certain amount of difference in detail, Fitt selects for contrast (with suitable reversal in the Southern Hemisphere): (1) birth months May to October, corresponding approximately to conception months August to January; (2) birth months November to April, corresponding approximately to conception months February to July. Children falling into these two groups will for conciseness be described in this paper as winter and summer children respectively.

### The Alternative Explanations

Two explanations of the difference are possible: first, the season of conception influences intelligence; or, secondly, the intelligence influences season of conception. Now, it is a remarkable fact that, with one partial exception (so far as I am familiar with the literature), every investigator has assumed without discussion that the first explanation must be the correct one. Some of the hypotheses advanced are outside the range of orthodox biological opinion—for example, the "the higher metabolic level of parental protoplasmic vigor during winter cold seems to be transmitted through the germ plasma, and to exert a lasting effect upon the future course of the offspring." There would seem to be nothing inherently unlikely, however, in the assumption that the prenatal environment of the developing child is more favourable at one season as compared with another. This would be an interesting addition to the list of known non-genetic prenatal influences such, for example, as the well-known effect of advanced maternal age in mongolism, or the effect of being a first-born child in congenital pyloric stenosis (Cockayne and Penros 1943).

The partial exception to this unanimity of opinion is provided by Huntington (1938). His observations on such material as highly gifted persons have led him to postulate a favourable season which is different from that indicated by the large-scale studies. He is concerned to explain the discrepancy, and states (p. 325): "It seems highly probable that the three types here mentioned—namely, the passionate, the unintelligent, and the weak-willed—contribute more than their proportional share to the excess of births which still occurs at the height of the animal rhythm. We should expect many of the children of such parents to have low intelligence, and they might well suffice to overbalance the unusually bright children who are born at the same season, thus giving a low average I.Q." In regard to his main thesis, however, he is convinced that it is the season which affects intelligence. Thus he states (p. 441): "Our new knowledge as to season of birth can be of practical use only if we use it in one of two ways. First, we can change the present seasonal distribution of births. Secondly, we can discover the exact conditions which make certain seasons favourable, and then take steps to create those conditions in other seasons."

### Practical Importance of the Problem

Apart from the theoretical interest of the problem, the practical importance of deciding which explanation is the right one is not inconsiderable. Many writers carry the argument to its logical conclusion and urge that a planning of season of conception would aid in human betterment. To choose one example, Mills (1941) sums up as follows: "The findings reported in these pages have a very direct bearing

upon human eugenics. Present-day civilization is dominated much more largely by mental achievement than by physical, hence the importance of stressing eugenic factors that promote mental functions. It would seem highly desirable, therefore, that parents keep in mind the advantages offered their offspring by winter conception. Even the best hereditary background may be made much more effective if supported by proper season of conception."

It is true that the average difference is a small one, but many persons might reasonably feel that the demonstration of a real advantage attaching to one season was an indication that it is physiologically preferable for mother and child that conception should occur during the winter months.

If, however, the alternative explanation is the true one, and it is the intelligence of the parents which influences season of conception, the intelligence of the children of any particular pair of parents would be entirely unaffected. In fact, if Huntington is right (I have no data to offer in this connexion), advice based on the mass studies would be not only useless but positively harmful.

#### A Crucial Test

Perhaps the simplest way of distinguishing between the two possibilities is the method suggested above. Children born to the same parents can be compared—i.e., winter children can be compared with their summer brothers and sisters. If season of conception influences intelligence the usual difference will be found. If, on the other hand, intelligence influences season of conception there will be no difference.

A second line of inquiry is to determine the number of sibs of comparable groups of winter and summer children. Should it be intelligence which influences season of conception, winter children will not only be more intelligent but will have fewer brothers and sisters.

The evidence I have to offer on both these lines is not based on very large numbers, and it is to be hoped that others with more ample material available may be able to put the matter beyond reasonable doubt. Nevertheless, even on the data presented in this paper it is strongly indicated that, unfortunately, the less interesting explanation is the true one. It is the intelligence of the parents which influences the season of conception of the child. Hypotheses of the type almost universally put forward, all depending on the reverse proposition, are, as regards the mass studies at least, inadmissible.

#### The Material

The material is based on a sample of school-children and has already been used for a number of purposes, as described in a series of papers by my colleagues Dr. R. M. Norman and Dr. Ruth Griffiths and myself (1935, 1937, 1938a, 1938b, 1940). Briefly, an attempt was made to secure a representative cross-section of the school-child population by ascertaining, and giving a mental test to, every child whose home was within the boundaries of the City of Bath on July 27, 1934, and whose date of birth fell between Sept. 1, 1921, and Aug. 31, 1925, inclusive. It is believed that ascertainment and testing were in fact almost complete; full particulars are given in the papers quoted. The number of tested children was 3,361.

The sample included a number of sets of sibs, and so provides material for the test mentioned above. Also, in smaller groups chosen from the main group a fuller family study was made. This involved testing all available sibs of school age, and so provides a further sample of sets of sibs. Finally, the number of living full sibs of nearly all the children composing the whole group was determined, so that the second line of inquiry can also be pursued.

#### Results

In the first place, taking the whole sample of 3,361 children, the following figures show that, just as in the studies summarized by Fitt, winter children have a somewhat higher mean performance than summer children. The test used was the advanced Otis; and the index of brightness, or I.B., is centred in 100, with a standard deviation which is about double that of Binet I.Q.

	No.	Mean I.B.
Winter children ..	1,701	100.792
Summer children ..	1,660	99.087
	Difference = 1.705 ± 1.200	

The difference is 1.42 times its standard error. If, however, account is taken of the fact that the deviation is in the expected direction, it just attains the level of significance. There is, of course, some doubt as to where the seasonal limits should be fixed, and with fuller knowledge it would be possible to make more efficient comparisons than that between two six-month periods. It may be worth mentioning that in this sample if February children are transferred from the summer to the winter group the difference becomes significant, even apart from direction.

The whole group included 244 pairs of children born to the same parents, one in each case being a winter child, the other a summer child. This provides 244 differences in Otis I.B.—positive when the winter child is the brighter, and vice versa.

There were 38 sets of three in each of which one child fell into one season and two into the other. Each of these sibships provides two comparisons. It seems reasonable to attach a weight of 1 to each difference between a pair—i.e., a weight of 0.5 per single child. Hence each of the 76 comparisons due to sets of three has been given a weight of 0.75. Similarly, a set of four—three and one respectively falling into the two seasons—provides three comparisons, each with a weight of 0.6. One other set of four—two falling into each season—provides four comparisons, each being allotted a weight of 0.5.

The comparison is thus equivalent to one of 305 pairs of children, each born to the same parents, one member of each being a winter child, the other a summer child. The difference proves to be  $+0.299 \pm 1.820$ . The winter children are still slightly superior, but the difference has been reduced to negligible proportions.

The other sample provides stronger evidence. The cleverest, the median, and the dullest children were chosen for special study, and an attempt was made to test every sib of school age. A group of families of cousins was also tested. The test used was the Stanford-Binet. There is provided in this way a sample of sets of children ranging from one to seven sibs. Unlike the main sample, it is not, of course, either random or representative, but the effect of selection is the same for both winter and summer children. Actually, the mean I.Q. proved to be fairly close to 100.

In the case of 332 children, those born to each pair of parents fell into one season or the other. The result is:

	No.	Mean I.Q.
Winter children ..	172	101.465
Summer children ..	160	97.963
	Difference = 3.502 ± 1.992	

Once again the winter children are superior, the difference being 1.76 times its standard error.

In the sets of sibs which included both winter and summer children the same method of weighting was used as is described above. For example, a set of 7, with 4 falling into one season and 3 into the other, provides 12 comparisons, each being allotted a weight of  $3.5/12$ . There is provided a comparison equivalent to that of 164.5 pairs. The result is  $-1.943 \pm 1.240$ . Thus a large difference, significant if direction is taken into account, is converted into a considerable difference in favour of summer children when sibs born to the same parents are compared. The reversal is significant.

In the main group the number of living full sibs was determined in 3,305 instances. The result is as follows:

	No.	Mean No. of Sibs
Winter children ..	1,676	2.511
Summer children ..	1,629	2.649
	Difference = -0.138 ± 0.076	

The winter children have fewer sibs, the difference being 1.82 times its standard error.

In the whole group winter children differ from summer children by 1.705 points of I.B. This is 0.049 times the standard deviation of I.B. But they differ in number of sibs by 0.063 times the standard deviation of sib-number. Thus while winter children do differ from summer children in intelligence, they differ even more in regard to the lower fertility of their parents. This alone makes it likely that the difference in intelligence

is to be ascribed to a tendency for the time of conception of children to vary at different levels of parental intelligence.

Moreover, there is little doubt that the difference in fertility has been underestimated. The number of living full sibs was ascertained at a time when many of the families were incomplete. Evidence has previously been presented (Roberts, 1939) to show that, when allowance is made for this circumstance, fertility differences are considerably increased.

Taking the evidence as a whole, the results can be said to be significantly against the hypothesis that season of conception influences intelligence, and therefore in favour of the alternative explanation—that intelligence influences season of conception.

### Summary

It is a fact beyond reasonable doubt that children conceived in winter are, on the average, somewhat more intelligent than those conceived in summer. The fact has been almost universally misinterpreted. Practically every hypothesis depends upon the assumption that it is season of conception which influences intelligence, and it has often been urged that planned winter conception would be beneficial. It is shown that if winter children are compared with their summer brothers and sisters the difference vanishes. It is also shown that while winter children differ from summer children in intelligence, they differ even more in having fewer sibs. Thus the observed association is to be ascribed not to seasonal influences on the mother or the developing child, but to a tendency for the children of more intelligent parents to be conceived slightly more often in winter, those of less intelligent parents slightly more often in summer.

## BACILLARY DYSENTERY IN DUNDEE

### A COMPARATIVE STUDY OF TREATMENTS

BY

W. M. JAMIESON, M.D., D.P.H.

Senior Resident Medical Officer, King's Cross (Infectious Diseases) Hospital, Department of Public Health, Dundee

J. BRODIE, M.D., D.P.H.

AND

D. STIVEN, D.Sc., Ph.D.

Department of Bacteriology, University of St. Andrews Medical School, Dundee

The treatment of bacillary dysentery by sulphaguanidine has opened new fields of investigation. Much of the recent work on this subject has dealt mainly with clinical recovery, but correlation thereof with bacteriological clearance of the stools has received less attention. In this paper are set forth the clinical and bacteriological results obtained in 200 confirmed cases of bacillary dysentery which occurred in Dundee.

Prior to 1941 the criterion for discharge of cases of dysentery from King's Cross (Infectious Diseases) Hospital, Dundee, was purely clinical—i.e., the reversion to normal stools for a period of approximately four days. Late in 1941 examination of faeces in convalescence was undertaken to determine the "convalescent" carrier rate and so find out whether the discharge of patients on clinical evidence alone was possibly contributing to the maintenance of the infection in the community.

The investigation, begun in this way, was extended to a study of the effects of different methods of treatment not only on the course of the disease but also on the incidence of the carrier state in convalescence. The first specimen of faeces in convalescence, irrespective of the treatment adopted, was examined four to six days after the disease had subsided clinically—i.e., at the time when by former standards the

patient would have been discharged from hospital. Thereafter faeces were examined twice weekly until three consecutive negative results were obtained.

The gross figures for bacillary dysentery from 1937 to Aug. 31, 1943, are set forth in Table I.

TABLE I

Year	Notifications	No. Admitted to Hospital	No. Accepted Clinically	No. Confirmed Bacteriologically	Clinical Cases Confirmed Bacteriologically (%)
1937	47	50	23	13	57
1938	325	271	141	45	32
1939	172	169	96	40	42
1940	390	279	183	78	43
1941	420	275	153	73	48
1942	421	322	213	148	69
1943 (8 mths.)	173	130	91	65	71

The table shows that, with the exception of 1939, there was a steady, if slight, increase in the number of notification. There was also a steady rise in the percentage of clinical cases confirmed bacteriologically since 1938. In 1937 the numbers were so small that comparison with 1938-4 cannot be made. This steady rise can be ascribed to improvements in laboratory technique. For about 15 years prior to 1939 faeces were collected in outfits containing Teague's flu (Teague and Clurman, 1916) and plated direct on neutral red agar (MacConkey, 1908). In 1939 Sachs's (1939) modification of Teague's fluid was adopted and MacConkey's agar was modified in that the nutrient basis became serum-peptic-digest lemco broth (Brodie, 1942). Towards the end of 1941 a selective solid medium and a fluid enrichment broth for the isolation of *B. dysenteriae* and pathogenic members of the colon-typho group were elaborated. These consisted of serum-peptic-digest lemco-bile-salt-iron-citrate-rosolic-acid-lactose (C.R.A.) agar at the corresponding C.R.A. broth (Brodie, 1942). The flu medium has since been modified by the omission of the factor but the sugar must not be omitted from the solid medium.

It will be seen that the percentage of bacteriologically confirmed cases rose with these various improvements in laboratory technique. The present investigation covers the whole of 1942 and 1943 up to Aug. 31, and during this period the media employed for isolation were C.R.A. agar and C.R.A. broth.

### Methods of Treatment

The series comprised a total of 200 cases, all confirmed both clinically and bacteriologically. Three types of treatment were adopted, as follows:

(a) *Aperients* (50 Cases).—An initial dose of ol. ricini was given followed by thrice-daily doses of milk of magnesia for children and of sodium sulphate for adults, the dosage being reduced as abnormal constituents disappeared from the stools.

(b) *Sulphaguanidine* (100 Cases).—At first the dosage used was small, being in accordance with that suggested by Anderson and Cruickshank (1941); but both clinical and bacteriological results were disappointing, as no fewer than 12 out of 15 cases so treated yielded positive cultures in convalescence. All 15 cases were infections due to *B. dysenteriae* (Flexner). No further reference is made to these cases. In consequence of this result and because large doses were advocated by Marshall *et al.* (1941), increased dosage based for convenience on age instead of body weight, was instituted (Table II). The tablets were crushed and given in water, the daily dose being divided into four equal six-hourly portions. In all, 11 cases were so treated, and no toxic effects from the drugs were observed.

TABLE II.—Dosage of Sulphaguanidine

Age in Years	Grammes per Day					Total in Gramme
	1st	2nd	3rd	4th	5th	
0-2 .. ..	6	2	2	2	2	14
2-5 .. ..	10	4	4	4	4	26
5-12 .. ..	20	6	6	6	6	44
Over 12 ..	30	8	8	8	8	62

(c) *Chalk Mixture* (50 Cases).—Large doses of sulphaguanidine have a constipating action. It was decided, therefore, to employ the third group a simple remedy—namely, chalk—which would produce a similar effect without exerting the inhibitory qualities of the dysentery bacillus claimed for sulphaguanidine. The amount

of chalk administered for each age group was twice the weight of sulphaguanidine shown in Table II. On several occasions this treatment was supplemented by the oral administration of tinct. opii.

In all groups abundant fluid was given orally, and parenterally when required. There were no special dietary restrictions.

### Clinical Features

Most of the cases occurred in children under the age of 10 years—only 25%, approximately, being over that age. Pyrexia was not a notable feature, and when present it usually subsided within 48 hours of the beginning of treatment. The clinical appearance of the stools varied between loose offensive motions and the typical "pus-blood-and-mucus" dysentery stool. The clinical features are summarized in Table III. No fatal case was encountered in the series.

TABLE III

Type of Treatment	No. of Cases	No. with Pyrexia		Appearance of Stools		
		95-4 F to 100 F	Over 100° F.	Blood and Mucus	Mucus	Loose
Aperients	50	11	9	17	30	1
Sulphaguanidine	100	15	15	44	49	7
Chalk	50	11	7	33	14	3

### Clinical Results of Treatment

Disappearance of mucus from the stool with return to normal consistency was regarded as "clinical cure." The average duration of symptoms after admission is shown in Table IV, the cases being subdivided according to method of treatment and type of infecting organism.

TABLE IV

Type of Treatment		Type of Organism				All Types
		Flexner	Newcastle	Sonne III	Mixed	
Aperients	No. of cases	16	21	11	2	50
	Av. dur. symptoms (days)	6.4	7.0	6.3	4.5	6.5
Sulphaguanidine	No. of cases	51	34	10	5	100
	Av. dur. symptoms (days)	4.8	4.9	4.7	8.0	5.0
Chalk	No. of cases	6	23	18	3	50
	Av. dur. symptoms (days)	4.0	5.3	7.6	6.3	6.0

So far as "clinical cure" was concerned, sulphaguanidine treatment yielded better results than did aperients. In the chalk series duration of symptoms in Flexner and Newcastle infections approximated to the corresponding subdivisions in the sulphaguanidine group, whereas with Sonne III infections sulphaguanidine seemed to give better results. Furthermore, in the sulphaguanidine group the type of infecting organism did not materially alter the duration of symptoms. The mixed infections in each treatment group were too few to allow of comparison.

The incidence of relapse in each group was fairly constant, there being 5 instances in the aperient series, 10 in the sulphaguanidine, and 4 in those treated with chalk.

### Bacteriological Results of Treatment

The bacteriological findings in convalescence are shown in Table V. In this table "negative" means that in convalescence no dysentery bacilli were isolated, while the term "positive" indicates that micro-organisms were recovered from one or more specimens.

TABLE V.—Bacteriological Findings in Convalescence

Type of Treatment		Type of Organism				All Types
		Flexner	Newcastle	Sonne III	Mixed	
Aperients	No. of cases negative	8	10	7	0	25
	% pos. after treatment	8	11	4	2	25
Sulphaguanidine	No. of cases negative	50	52.4	36.4	100	50
	% pos. after treatment	36	26	6	2	70
Chalk	No. of cases negative	15	8	4	3	30
	% pos. after treatment	29.4	23.5	40	60	30
	No. of cases positive	5	12	7	0	24
	% pos. after treatment	16.6	47.8	61.1	100	52

On the whole the group of cases treated with sulphaguanidine gave better results than did either of the other groups, although treatment of Sonne III infections with aperients was slightly better than with sulphaguanidine. The low percentage of positive cases in convalescence in the chalk-treated Flexner group cannot be considered a fair comparison owing to the small number of such cases in the series.

The isolation of *B. dysenteriae*, using the media herein described, can be obtained either by direct plating on C.R.A. agar or by subculture following enrichment in C.R.A. broth. An analysis of the isolations obtained by plating compared with those obtained only after enrichment is interesting, and is shown in Table VI.

TABLE VI.—Analysis of Isolations

	Aperients	Sulphaguanidine	Chalk	All Types
No. of diagnostic specimens positive by direct plating	33	70	33	136
No. of diagnostic specimens positive after enrichment only	8	21	12	41
No. of convalescent specimens positive by direct plating	29	24	35	88
No. of convalescent specimens positive after enrichment only	11	21	18	50

It will be noted that there is an apparent discrepancy between the number of positive diagnostic specimens and the total number of cases. This is due to the fact that in 23 cases the infecting organism was isolated only during convalescence. These specimens were therefore considered as convalescent specimens.

The results in Table VI show that the employment of the enrichment technique is amply justified and that direct plating, used alone, can yield a false sense of security as regards freedom from infection. Particularly is this so in convalescence, where no less than 36% of the positive results were obtained only by the enrichment method. Moreover, a number of cases included in this investigation would not have been confirmed bacteriologically and a further number would have been discharged prematurely had not the enrichment technique been employed. These are set out in Table VII.

TABLE VII

	Type of Treatment			Total
	Aperients	Sulphaguanidine	Chalk	
No. of cases with specimens positive at all stages, but by enrichment only	9	18	7	34
No. of cases in convalescence with all positive results obtained only by enrichment	6	11	3	20

It might be thought that laboratory technique would have no great bearing on the management of cases, but, as will be seen in Table VII, the greatest number of convalescent cases which yielded positive results by enrichment alone fell to the sulphaguanidine group. Moreover, Table VI shows that of a total of 45 positive specimens during convalescence in the sulphaguanidine group, 21 would have yielded false negative findings had enrichment not been used.

The convalescent carrier rate in the sulphaguanidine series, then, is lower than in the other two, but the difference would have been even more striking had only direct plating been employed: for without enrichment the percentage of cases positive after sulphaguanidine would have fallen from 30 to 19%, as compared with from 50 to 38% and from 52 to 46% after aperients and chalk respectively. Furthermore, a certain number of cases which were positive in convalescence by direct plating yielded subsequent positive specimens by enrichment only, therefore prolonging their stay in hospital. Because of this, in 19 cases in the sulphaguanidine group an average of 9.9 days per case was added, while in the aperient group 9 cases were similarly delayed for an average of 7.6 days and in the chalk group 9 cases for 5.5 days.

It may be that the explanation of this prolongation of the "convalescent" carrier rate, particularly in the sulphaguanidine

group, is due to the small number of dysentery bacilli in the faeces—small because of the inhibitory action of sulphaguanidine on the micro-organisms. This will have a direct effect on isolation of the micro-organisms, since if their number be small, so will the possibility of isolation by direct plating be small, whereas "enrichment" in C.R.A. broth followed by plating on C.R.A. agar will enhance the chance of their isolation.

In the aperient group the delay was less than in the sulphaguanidine group but greater than in the chalk. Here the bacilli are washed out of the gut mechanically by purgation, but, since no inhibitory effect is present, propagation of the remaining bacilli can continue unimpeded. Under such conditions direct plating should give more satisfactory results, and so "enrichment" could be expected to exercise less effect in delaying the discharge of convalescent cases from hospital.

Since chalk has a purely mechanical action in producing constipation, the organisms are more likely to be present in larger numbers in the gut, and so direct plating might be expected to give the optimum number of isolations, making the enrichment technique less necessary, and therefore less apt to prolong the "convalescent" carrier rate.

Whether or not the above explanations are correct, the results obtained do indicate the necessity for exercising great care in the handling of faeces from convalescent cases, especially where drugs possessed of properties inhibitory to the dysentery bacilli are employed in treatment.

#### In Vitro Experiments with Sulphaguanidine

Marshall *et al.* (1940) claim that sulphaguanidine *in vitro* possesses inhibitory, bacteriostatic, or bactericidal effects on the micro-organisms of the dysentery group. The optimum temperature for these effects varies from 39° C. to 41° C., and these temperatures are worthy of note, since their occurrence *in vivo* depends upon the clinical severity of the cases. In the 100 cases surveyed only 30 were pyrexial, and of these 4 had a temperature over 39° C. In view of the claims of Marshall *et al.*, these pyrexial cases treated with sulphaguanidine in sufficient quantity to produce saturation of the gut contents should show the maximum benefit from treatment.

The *in vitro* experiments were designedly performed at 37° C. because of the preponderance of apyrexial infections encountered among the cases discussed. Six smooth and recently isolated organisms were employed—namely, *B. typhosus*, *B. paratyphosus* B, *B. dysenteriae* (Shiga), *B. dysenteriae* (Flexner W), *B. sonnei* III, *B. dysenteriae* var. Newcastle. All were grown for 24 hours in 1% peptone water before subculture into media containing sulphaguanidine. Two loopfuls (1/8 in. diameter) of this growth were used in each instance to inoculate agar slopes, semi-solid agars, and broths, all made according to the method of Hinton (1918), enough sulphaguanidine having been added to the media to ensure saturation at 37° C., and all tubes being incubated at that temperature after addition of the drug and before inoculation. Subcultures were made at intervals of 24, 48, 72, and 96 hours into 1% peptone water. Visible growth was not accepted unless all subcultures were checked by fermentation and serological tests. In no instance was a bactericidal action revealed on the solid medium, although a bacteriostatic effect was obtained with *B. dysenteriae* (Shiga), but subcultures even in this instance yielded good growths. All the other micro-organisms tested were inhibited, but bacteriostasis was not complete or even striking.

*In vitro* experiments at temperatures higher than 37° C. were not performed, but the possible effect of pyrexia on the course of the illness is indicated in Table VIII.

TABLE VIII.—Pyrexia in Sulphaguanidine Group

Bacteriological Findings in Convalescence	Normal Temp.	Degree of Pyrexia		
		Normal to 38° C.	38° C. to 39° C.	Over 39° C.
No. of cases negative ..	49	11	7	3
" " positive ..	21	6	2	1
Total ..	70	17	9	4

It would seem, therefore, that the occurrence of pyrexia in sulphaguanidine-treated cases has no marked influence on the bacteriological results in convalescence. It is interesting, however, to contrast the pyrexial with the apyrexial cases in respect of average duration of symptoms following treatment. The average duration in the 30 pyrexial cases was 4.6 days, as compared with 5.2 days for the 70 apyrexial cases. This would suggest that sulphaguanidine is somewhat better in respect of clinical recovery in the more acute type of case. During the period covered by this investigation 5 cases of chronic bacillary dysentery have been treated at varying times with full courses of sulphaguanidine (Table II). In none of these has any improvement in the clinical—or bacteriological—condition been observed following such treatment.

#### Estimation of Sulphaguanidine

When using sulphaguanidine it is essential to oversaturate the gut contents with the drug. The solubility of sulphaguanidine at body temperature is approximately 200 mg. per 100 c.cm.; therefore the presence of more than this amount can be taken as evidence that saturation has been achieved. Two patients in each age group were investigated as to the amount of free sulphaguanidine in their stools at 24-hour intervals after starting treatment. The method of estimation was that recommended by Bratton and Marshall (1939). The results are shown in Table IX.

As a matter of interest a few urines were also examined for their free sulphaguanidine content per 100 c.cm., and these results are entered in parentheses in their appropriate places in the table. From the figures obtained it is apparent that, despite the claim that sulphaguanidine is not absorbed from the gut to any great extent, an appreciable amount can be demonstrated in the urine.

TABLE IX.—Concentration of Free Sulphaguanidine in Faeces (mg. per 100 g.)

Age Groups (years)		Time of Sampling after starting Treatment				
		24 hrs.	48 hrs.	72 hrs.	96 hrs.	120 hrs.
0-2	Case 1	4,430	456*	1,970	1,450	1,260
	" 2	688*	535*	892	621	876
2-5	" 3	5,450	5,165	6,700	4,274	1,587
	" 4	838	6,180	866*	1,560 (100)	1,493 (93)
5-12	" 5	4,710	6,350	4,388	2,038 (133)	1,877 (154)
	" 6	2,320	3,630	2,720	3,780 (29)	2,255 (58)
Over 12	" 7	13,300	5,430	7,190	4,430	No specimen
	" 8	10,800	3,030	2,850	1,965	1,240

\* Fluid stool.

It is evident from the results in Table IX that the dosage adopted, based on age in place of body weight, besides being more practicable, is also quite adequate to oversaturate the gut contents.

#### Conclusions

The use of sulphaguanidine in bacillary dysentery gives results superior, both clinically and bacteriologically, to those from aperients and chalk, but, even so, 30% of cases are still bacteriologically positive in convalescence, as compared with 50% with the other treatments.

Pyrexia does not appear to influence the effect of sulphaguanidine to any great extent.

The use of the C.R.A. broth-enrichment technique reveals many positive results, particularly in convalescence and in cases treated with sulphaguanidine, which would be missed if direct plating only were employed.

We wish to thank Prof. W. J. Tulloch and Dr. W. L. Burgess for facilities granted in the preparation of this paper.

## MENINGOCOCCAL JAUNDICE

BY

CHARLES CRAWFORD, M.R.C.S., L.R.C.P.

Capt., R.A.M.C.; Attached to a Military Hospital

Simple infective hepatitis becomes a common disease in war-time, and the other diseases giving rise to jaundice are infrequently met with in healthy young soldiers, so that the occurrence of one of the rarer causes may be worth recording. This case had jaundice as the unusual presenting symptom of a severe acute meningococcal septicaemia, and it is of interest, first, because there were never any symptoms of meningeal involvement, and, secondly, because it was not until the patient was well on the way to recovery, as a result of empirical treatment, that a final diagnosis was made.

## Case History

The patient, a soldier aged 23, was admitted to hospital on the second day of an illness which started after an inoculation of T.A.B. and tetanus toxoid. Previously he had been quite well. Five hours after the injection, after dinner, he began to shiver and feel sick, vomiting several times during that and the following day, and twice bringing up fairly copious streaks of blood. Twenty-four hours after the onset he noticed that his urine was dark, and at this juncture he was admitted to hospital.

Physical examination gave one the general impression of a not very ill man. His conjunctivae and skin were moderately jaundiced, and the tongue was furred, the liver was enlarged to two finger-breadths below the costal margin and was tender, and the spleen was not palpable. His temperature was 98°. The urine contained bile and a moderate amount of albumin, and a diagnosis was made of simple infective hepatitis, with symptoms accentuated by the T.A.B. inoculation. He denied having had any arsenical injections, although he had had gonorrhoea. Next day, however, his temperature had risen to 103°, severe frontal headache was present, and a rash had appeared, at first red and macular in character and confined to the trunk, and later becoming purpuric. Neck rigidity was absent and Kernig's sign was negative. A blood count showed 3,620,000 red and 18,700 white cells. He had vomited only once since admission and was taking fluids well; but, although he was rational, he was obviously more ill than would be accounted for by a simple infective hepatitis, so a tentative diagnosis of Weil's disease was made.

None of us had seen a case of Weil's disease, but a leucocytosis of 18,700 eliminated infective hepatitis and the enteric group, and the general picture of jaundice, pyrexia, purpuric rash, and albuminuria made the diagnosis probable, although the two signs stressed in the textbooks—muscular pains and suffusion of the eyes—were absent. Any pneumonic condition was ruled out by physical examination and radiographs of his chest, and the only factor difficult to account for was the speed at which jaundice had appeared, there being practically no prodromal phase; but this we explained by the exaggerating effect of the T.A.B. Further questioning showed that exposure to rats was possible. He had been in Kent for two months before the illness, and had slept under canvas, but he denied bathing in or drinking from unauthorized water sources, and his only wet job had been potato-peeling. He had, however, seen several rat-holes in the vicinity of the tents, and heard rats about at night.

So although the diagnosis rested on rather slender evidence, it was the best we had to go on; culture of the T.A.B. and T.T. had proved sterile, and none of the other men inoculated from the same bottles at the same time had had any unusual symptoms. Accordingly, blood was taken for culture and for guinea-pig inoculation, and he was given daily 60 c.cm. of antileptospiral serum, urgently obtained by dispatch rider. Ample fluids were given by mouth, together with 300 g. of glucose and 150 units of insulin, as well as 1 g. of calcium gluconate daily, to minimize liver damage. There was only enough serum for three days' treatment, but by the end of that time, instead of improving, his condition had deteriorated, the temperature being irregular, and varying between 98° and 104°, the rash spreading over his limbs and face, and his skin assuming a greenish tinge, although, apart from severe frontal headache, he did not appear to feel very ill. There was still no neck rigidity or positive Kernig's sign, and blood taken three days before, on the third day of illness, was sterile on culture. His blood showed no agglutination to leptospiral serum, so our hopes turned on the fate of the guinea-pig. By the end of ten days, however, the patient was still extremely ill and severely jaundiced, although the rash had faded a little, and his temperature was swinging considerably; so, to shake our diagnosis further, the guinea-pig, which by this time should have been moribund, was thriving with no untoward symptoms.

A consultation was held to decide on further action, as it was now clear that our diagnosis was wrong, and that he was not

responding to treatment. Blood was again taken for culture, and a count showed 3,620,000 red and 22,400 white cells. As a last resort, and against all best principles in an undiagnosed case, it was decided to try the effect of one of the sulphonamide drugs. We gave him sulphathiazole and, lest we should further damage the liver, only a moderate dose was used—1 g. four-hourly, after an initial 2 g. The result was dramatic (see temperature chart). Within 24 hours his

Chart of the case, showing temperature and white cell counts.

temperature dropped to 95°, and never rose above normal again; he was feeling better, and for the first time since admission asked for something to eat. A day later the jaundice was fading and his urine was free from bile.

It was not until this stage that the thought of some common septicaemic condition was seriously entertained. The swinging temperature, the purpuric rash, the albuminuria, the liver damage, and the leucocytosis all fitted in, but the degree of jaundice was an outstanding difficulty. Apart from this, the fact that the organism had not so far been cultured, and the dramatic response to chemotherapy, suggested the meningococcus as a possible causative organism, as it is notoriously difficult to grow. Finally, on the next day our minds were set at rest, and the diagnosis was finally established by a telephone message from the pathologist reporting the growth of a Type 1 meningococcus after seven days' culture.

Altogether the patient had 28 g. of sulphathiazole over four days, and once his temperature had resolved his jaundice cleared quickly, his appetite returned to such a degree as to make up for the two-weeks lack of solid food, and, apart from a severe serum reaction with urticaria of his skin and mild oedema of the glottis ten days after the antileptospiral serum, and a mild relapse of the jaundice two weeks after the resolution of his temperature, he made a complete recovery.

## Discussion

There are several points of interest in this case—first we have the severity of the jaundice and its early appearance, within 24 hours of the onset. It must be exceedingly rare, apart from Weil's disease and yellow fever, to encounter severe jaundice and prolonged high fever in a patient who has not some obvious reason for his liver damage, such as portal pyaemia or suppurative cholangitis. The localization of the infection to the liver is also noteworthy, in view of the complete absence of meningeal involvement even after ten days' septicaemia.

As for our lateness in forming a diagnosis, the jaundice was the red herring, without which we should probably have been on the right track much earlier. The high fever, the leucocytosis, and the purpuric rash would have helped but for the fact that they also fitted the descriptions of Weil's disease; and at the time, before the bacteriological reports were returned, everything was in favour of this diagnosis, except for the absence of suffusion of the eyes and the muscular pains, which are always present and are often agonizing. These two signs we later learned to be almost constant findings.

Last of all, the improvement of the condition so soon after sulphathiazole had been started made us a little doubtful whether the drug was the curative agent or whether we were witnessing the natural history of the disease; but although the patient's temperature had returned to normal within 18 hours of starting the drug—i.e., after only 8 g. had been given—the permanence of its effect and the final isolation of the organism made its curative action a certainty.

## Summary

A case of meningococcal septicaemia is described in which the presenting symptom was severe jaundice—the meninges escaping infection—and in which at first a mistaken diagnosis of Weil's disease was made. Cure of the condition was dramatic, and resulted from the use of sulphathiazole.

My thanks are due to Lieut.-Col. E. Bulmer for his advice in publishing this article.

## Medical Memoranda

### Staphylococcal Septicaemia treated with Penicillin

The following record of a case of septicaemia which responded to treatment with penicillin may be of interest.

#### CASE HISTORY

The patient, a lance-corporal aged 21, had been treated for sinusitis two months before the present illness, and had had several examinations on account of chronic cough; these were Tb-negative. Two weeks before admission to hospital he had had a boil on the neck, which healed on being opened and drained. Five days before admission he reported sick with acute pain over the right sacro-iliac region. There were no other symptoms, and no pyrexia. He was treated at home with local heat. An unusual feature was the extreme tenderness. Just before admission to hospital his temperature was 102° and the pulse 107. There was oedema of the right buttock and slight diarrhoea.

On Nov. 22, 1943, at 6 p.m., the patient was admitted to the Royal Hospital, Richmond. His temperature was then 103° and the pulse 120, and he complained of severe pain in the right buttock and the right shoulder. Aspiration of the buttock yielded a few cubic centimetres of thick pus, which proved to contain *Staph. aureus*. Sulphathiazole 2 g. was given three-hourly for 3 doses, followed by 1 g. four-hourly. Culture of blood collected at 5 p.m. on the next day gave a heavy growth of *Staph. aureus*.

On Nov. 23 deep abscesses of the buttock and the supra-acromial region were opened and drained. The patient's temperature was still raised and his general condition poor. Sulphathiazole administration was continued until 2 a.m. on the 24th. The concentration of drug in the blood was very low (between 1 and 3.5 mg. per 100 ml.). The white cells numbered 25,000 per c.mm.

At 10 p.m. on Nov. 24 treatment with penicillin started with intravenous injections of 15,000 units (2.5 c.c.m.) three-hourly. The white cells were reduced to 17,600 per c.mm. On Nov. 25 the temperature was still swinging between 100 and 103°. His general condition, however, had slightly improved, with 14,000 white cells per c.mm. and 70% haemoglobin. A transfusion of one pint of stored blood was given on Nov. 26. The abscesses continued to drain, and the patient's condition was slightly better.

On Nov. 27, at 10 p.m., penicillin was discontinued after a total dose of 360,000 units had been given. On the 29th blood culture was sterile, and next day the temperature was normal. Further progress was uneventful. At the patient's discharge on Dec. 20 his general condition was good and the abscesses had healed.

All laboratory investigations were carried out by Miss Sheila Newstead, M.R.C.P.

### Rupture of the Rectus Abdominis Muscle during Pregnancy

In the *Journal* of July 31, 1943 (p. 136) there is an account by Rufus C. Thomas of a case of rupture of the rectus abdominis muscle during pregnancy. As I had such a case in 1937 I send a short account, since I feel that the rarity of this misadventure warrants publication.

The patient was a woman 30 years of age who was at term with her sixth pregnancy. Her obstetric history was entirely satisfactory, and the existing pregnancy had been attended by no untoward circumstance. She was admitted to the Duncedin Hospital on Aug. 16, 1937, complaining of spasms of epigastric pain for the preceding 24 hours, which had been replaced by a constant pain on the left side of the abdomen that was aggravated by movement. The pains did not resemble labour pains. She had suffered from a cold for about three weeks and severe cough with vomiting for three days before admission.

On examination she appeared to be a healthy obese woman with no signs of constitutional disease. Abdominal examination, hindered by a heavy overburden of fat, revealed two tumours of approximately equal size and symmetrically occupying the right and left halves of the abdomen from the pubes to the costal margins. That of the right was the uterus containing a foetus at term in the R.O.A. position and alive with satisfactory heart sounds. The left tumour was diagnosed as an ovarian cyst which had either rotated its pedicle or into which a haemorrhage had occurred; a definite fluid thrill was elicited. This seemed a reasonable diagnosis, although it may possibly have been influenced by the fact that a pregnancy with a large ovarian cyst had been dealt with in the hospital a few weeks previously.

The abdomen was opened in the midline below the umbilicus. The left-hand tumour was found to be a very large haematoma between the peritoneum and the anterior abdominal wall. It was as big as the pregnant uterus, which was displaced to the right. Fortunately the incision just missed opening the haematoma, which was left alone. The foetus was delivered by a classical Caesarean section in a state of asphyxia livida, from which it rapidly recovered. Convalescence was quite satisfactory, and 14 days after the operation the haematoma could still be palpated, but it gradually and completely absorbed.

This case was one of rupture of the left rectus abdominis muscle as the result of coughing and vomiting, but it differed from most of the reported cases in that there was at no time any anxiety about the patient. There were no signs of secondary anaemia in spite of the size of the haematoma: on admission the patient's temperature was 98° and her pulse 100. The operation, performed under gas-oxygen anaesthesia, was uneventful and the child robust and healthy.

In 1939, two years later, another pregnancy occurred, which proceeded to uneventful delivery at term after the appearance of mild toxæmic symptoms during the 40th week.

### Actinomycosis treated with Sulphapyridine

The following is the history of another case cured, apparently with sulphapyridine.

#### CASE RECORD

In March, 1942, a farm labourer aged 20, a particularly healthy individual, developed a swelling in the left masseteric region on the cheek which spread through the substance of the cheek to the lower alveolus in the region of the second premolar and first molar teeth. The diagnosis of actinomycosis was proved beyond doubt by recovering the organism from a little pus obtained from a small incision in the cheek. Radiographs confirmed the fact that the bone (mandible) was involved.

Treatment with Lugol's iodine, on the advice of Prof. Grey Turner after being kindly approached on the subject by Mr. Eric Young was started in March, 1942, and was continued in increasing and heroic doses to May, 1942. As the swelling did not subside he had a course of x-ray therapy in June and July, 1942; but his condition continued to deteriorate, and the x-ray therapist finally stated that it could not be overcome by x-radiation, and advised surgical measures. By this time the patient could barely open his mouth, and the swelling was very large externally, with two discharging sinuses above the angle of the left mandible.

Before resorting to surgery, however, it was decided to try the effect of Lugol's iodine again, and he continued to take this from Aug., 1942, to Aug., 1943. While on the iodine his swelling greatly subsided and he was much more comfortable, the impression being that the condition was kept under control but not cured. On two occasions he developed symptoms of iodism, and the drug had to be stopped temporarily. The iodism rapidly cleared up, but the swelling developed again in an alarming fashion each time, with recurrence of discharge from the sinuses. Even while on the iodine he would have periods of a few days when one of his sinuses would discharge a little. It therefore became obvious that complete cure could not be expected from iodine.

In the *British Medical Journal* of July 24, 1943 (p. 106), I read a report by Dr. A. McCloy of a case cured by sulphapyridine. Now during the interval between the employment of x rays and starting iodine again I had experimented with sulphapyridine, using the heavy dosage given for severe infections, and with no apparent response. I observed, however, that Dr. McCloy had used a rather different method of administration. His scheme of dosage was:

2 tablets four times a day for four days.  
No tablets for four days.  
2 tablets four times a day for four days.  
No tablets for four days.  
2 tablets four times a day for four days.

This scheme was therefore adopted in this case, and met with a triumphant success. Treatment was started on Aug. 11, and finished on Aug. 30, by which time all swelling had gone and he could open his mouth naturally. He has had no recurrence of swelling since then.

Perhaps it may be said that it is too early to count on a definite cure, but I feel the case ought to be reported in order to establish the effectiveness of Dr. McCloy's scheme of treatment. It seems that the method of administration is important in this disease and that cure can be obtained if the correct dosage is given. Evidently for a chronic infection of this type it is necessary to give, not a high dosage over a short period but a smaller dosage over a prolonged period.

In the Medical Research Council's War Memorandum No. 11—*The Medical Use of Sulphonamides*—the following statement appears at page 33: "Actinomycosis cases have been reported which apparently responded rapidly to sulphonamide therapy. . . . Other observers have failed to confirm this response, and they prefer treatment with potassium iodide and x rays. Further experience would be valuable. If sulphonamides are used, large doses of sulphathiazole or sulphapyridine should be given, for a severe infection."

If any apology is needed for reporting this case so fully, I feel the answer lies in the fact that this gives a little more experience, and negatives the suggested dosage given by the

I would like to thank Mr. Eric Young, Dr. C. Bellamy, and Prof. G. Turner for their kind help in this case.

Leck, Staffs.

R. W. BILLINGTON, M.B.

## Reviews

### BRITISH WAR SURGERY

*Surgery of Modern Warfare*. Edited by Hamilton Bailey, F.R.C.S. Sub-editor for Medicine, C. Allan Birch, M.D., M.R.C.P. Compiled by 76 contributors. Parts I and II, third edition (complete in 2 parts). (Pp. 321; illustrated, 15s. each part, plus 6d. postage.) Edinburgh: L. and S. Livingstone, 1944.

The early appearance of a third edition of this work is an indication of its popularity and its importance. We learn that the whole of the second edition was bought up by one of our Allies, whose discernment is commendable. Those practising war surgery will undoubtedly find this the most comprehensive and authoritative work on their subject which has appeared since the outbreak of the present carnage. The third edition of it is being produced in six parts, the first two of which are now to hand. These show evidence of a thorough revision of the earlier texts in order to incorporate recent experiences and discard the redundant or obsolete.

Parts I and II deal with war wounds, the manner of their infliction, their classification, bacteriology, and treatment, and such questions as resuscitation, transfusion, anaesthesia, and surgical materials and dressings. Among many well-known contributors we find the names of the professors of either general or special surgery in six of our universities, as well as those of consultants to the Forces and of many serving medical officers in all three fighting Services and in the Emergency Medical Service. This book may therefore be said to be widely representative of British surgery, and particularly British war surgery. With each edition it becomes more valuable, not only as a guide to the inexperienced in war surgery but as a record of what has proved valuable in its practice, and in this respect it must to some extent constitute a surgical history of the present war. In the third edition the defects of the first have been almost eliminated. When the first edition appeared many of the contributors had had little experience of the wounds and problems of blitzkrieg and all that it implies; as might have been expected, therefore, some articles were reminiscent of the 1914-18 war. Every war, however, is a new experiment, and it was not long before we all found that the present one was no exception, and that many ideas and practices had to be changed, in some instances radically. The book is essentially practical, attractive in appearance, and lavishly and well illustrated. For it we have the highest commendation.

### COWS' MILK

*This Milk Business: A Study from 1895 to 1941*. By Arthur Guy Enock. (Pp. 292; illustrated, 18s.) London: H. K. Lewis and Co. 1943.

The title of Mr. Arthur G. Enock's book, *This Milk Business*, is well chosen, affording as it does some indication of the wide field of interests over which the author ranges. As would be expected of a consultant dairy engineer who has spent much of his time on the technical aspects of milk processing, he deals mainly with the distributive side of the milk trade. The producer's side is not forgotten; indeed, one of the suggestions made for the improvement of our present supply is to set a bacteriological standard for all milk received from the farm. One of the fullest sections concerns the heat treatment of milk. The author is not content to give a simple description of the methods now available. He criticizes the high-temperature short-time method roundly, and points out that the existing requirements are quite insufficient to ensure that all the milk passing through the plant is adequately heated. This statement is supported by a record of personal observations. On the other hand, he makes a strong plea for the in-bottle system of pasteurization—a plea that will receive the cordial support of public health workers. The phosphatase test comes in for quite unmerited abuse. Admitted that, like all other tests, it has its weaknesses, it is nevertheless calculated to be of great service to the cause of pasteurization. We hope that the author will see fit to revise his views, or else support his objections by the test by more solid evidence than that which he adduces here. In the future organization of the milk industry the establishment of a national milk control board is recommended, whose

purpose it would be "to ensure the supply to consumers of clean milk, free from disease, of full nutritional character, and of a quality which will keep sweet for at least two days in summer weather." This is an ideal worth aiming at, and nothing short of a unifying body commanding the interests and services of all branches of the industry is likely to achieve it.

There is much more in this book than can be touched on in this brief notice; and all those who enjoy looking at a subject from the point of view of an individualist will gain both pleasure and profit from its perusal.

### "DAMAGED GOODS"

*Damaged Goods (Les Avariés)*. A play by Eugène Brieux. New English version by Sir John Pollock, Bt. (Pp. 64. 2s. 6d.) London: Jonathan Cape.

The play entitled *Les Avariés*, by Eugène Brieux, was first produced in France in 1902. Banned by the Censor, it made a deep impression on Paris intellectuals; the ban was removed and the play achieved a triumph. Sir John Pollock translated it into English and got it published in 1911. It was produced at the Little Theatre in February, 1914, but came under the Censor's ban until 1917, when J. B. Fagan produced it at the St. Martin's Theatre, where it ran for nearly a year; touring companies carried it all over the country. It was revived at the Whitehall Theatre in the latter part of 1943, the new version having been slightly altered by the translator in order to bring it up to date.

The policy of Brieux was undoubtedly to show up social abuses fearlessly, but it needed courage of a very high order to mention "the most unmentionable of all subjects" (to quote Mr. Bernard Shaw). In the early years of this century the subject of venereal disease was completely taboo in polite society, and the public ignorance of it abysmal; the disease was regarded as the wrath of God descending on man for his sins; yet the play was a success in France from the start. When translated into English it produced the same reactions: the Censor banned it and "high life" regarded it as a lecture or a tract, but the public realized its drama, its humanity, and its educational value. They wanted to know more about the "unmentionable disease," and they want to now.

There can be little doubt that *Damaged Goods* plays, and will continue to play, an important part in the campaign against V.D., mainly because it is outspoken—it shows what syphilis is, how it may be acquired, and how it may affect the unborn child. This play is essentially an indictment of ignorance; it is drama at its best, and as such appeals to the ordinary man and woman.

### Notes on Books

It may be well to recall that the Charity Organization Society consists of a federation of district committees within the London area, whose general principles of action are determined by a central Council. The primary object of the society is to give a definite aim to, and to direct into the most effectual channels, the large amount of benevolent force at work in England, and particularly in London. One of its undertakings is the compilation of an *Annual Charities Register and Digest*, of which the 51st edition, for 1944, has now been published by Longmans, Green and Co. This is a most useful reference book, giving information about the societies, associations, and other bodies that provide relief in affliction and distress of all kinds. There are 43 sections and a full index. Copies can be had from the C.O.S., Denison House, 296, Vauxhall Bridge Road, S.W., or from the publishers, price 10s. 6d.

*Whitaker's Almanack* for 1944 has now been published from 13, Bedford Square, London, W.C.1. The usual three editions will be available—the complete edition, cloth bound, with 1,024 pages at 10s.; the shorter edition, paper bound, with 724 pages at 6s.; and the library edition, with a section of coloured maps, bound in leather, at 21s. Urgent Government demands on printers and binders delayed publication, and the editor in his preface finds occasion once more to note the increase in the space occupied by details of Government and Public Offices. The *Diary of the War* records the achievements of the United Nations, and various statistical tables of post-war reconstructional interest have been added. The general index runs to 72 pages.

## Preparations and Appliances

### THE ST. MARK'S X-RAY ANTI-INCONTINENCE DEVICE

Dr. NORMAN P. HENDERSON, D.M.R.E., radiologist to St. Mark's Hospital, writes:

Between the years 1929 and 1930, while searching for the best method of carrying out the combined air-inflation technique in the x-ray examination of the colon, the following device was made to my design, and at that time was manufactured for me by Allen and Hanburys, Ltd., London, W.1. Essentially it comprises a double rubber bag or "balloon" which can be inflated with air by means of the small tube fixed to the lower and back part of the rubber device (Fig. 1). Through the centre of this "balloon" a circular channel has been moulded sufficient to permit the passage of a rubber catheter, and in this connexion one of the self-retaining variety is advocated, such as the de Pezzet, size 28 or 30.

FIG. 1.—The rubber device complete with catheter and air bellows.

The catheter is passed through the central channel of the rubber bag, and the appliance is now ready for insertion into the rectum. To facilitate passage of the catheter head through the proctoscope the head can be elongated by extending it in

FIG. 2.—A, Stylet for de Pezzet catheter. B, Catheter with stylet inserted. C, Stylet, catheter, and rubber "balloon" passing through the proctoscope. D, The proctoscope obturator removed.

the usual way by inserting the metal stylet supplied for this purpose. Next the air is expelled from the rubber "balloon" by collapsing the bag between the fingers, and the whole (catheter and "balloon") lightly lubricated with some sterile lubricant, preferably not vaseline, as the latter tends quickly to perish rubber. Now pass the collapsed "balloon" and catheter through a large-size proctoscope which has been

inserted into the patient's anus and gently push the device in the rectum. Finally remove the stylet and proctoscope. The rubber bag is now gently inflated by means of the small bellows until the pressure on the bellows taps just becomes resistant to light pressure between the finger and thumb (approximately 25 mm. of mercury). This is found to be sufficient to keep the device securely in the rectum, with the minimum of discomfort to the patient, and to prevent the average patient expelling it or allowing any of the enema to return outside the rectum. To make sure no air escapes from the "balloon," it has been found from experience that the best device for clamping the rubber air pipe end is an old pair of Spencer Wells forceps. The usual vulcanite taps supplied to instrument makers invariably leak and consequently the air pressure in the "balloon" collapses. If desired, a manometer can be inserted in the air pipe through a "T" piece to act as a guide for the beginner and so register the actual pressure within the "balloon" now lying in the rectum. This, however, can usually soon be discarded after a short experience in the use of the device. Patients with badly torn perineums or severe sphincter paralysis may require additional pressure by application of a wad of cotton-wool twisted round the catheter and pressed over the perineum. Should difficulty still be experienced, the special accessory compression tray (Fig. 3).

FIG. 3.—Special accessory compression tray. Note slots at either end of tray for fitting abdominal bandage strap.

can be slipped up over the catheter and adjusted in position externally over the perineum and held there by two bandage straps which pass around the abdomen. This additional pressure tends to check further expulsion of the device until the enema is administered. The accessory compression tray is only rarely required, and in the average case of bowel incontinence the use of the rubber device alone has been found to work perfectly. As the appliance really acts as a rubber air cushion within the rectum there is no danger to the rectal walls themselves.

A miniature "balloon" measuring 1 in. in length has been found equally useful for washing out, or filling, either limb of the colostomy. It works on the same principle as the larger device for rectal insertion, a child's catheter being used instead of the adult sizes.

During the past 14 years this appliance has been in active use, and so far no failures in its application have been recorded. It would appear to be invaluable to the medical practitioner or exasperated nurse for washing out colons in these difficult cases, and to the radiologist for the successful carrying out of the opaque enema on the incontinent patient, being specially recommended for the combined air-inflation enema cases that cannot retain the air in the bowel in sufficient quantity and require this to be held under slight pressure.

### LOCAL SULPHANILAMIDE THERAPY

"Wellcome" brand sterilized sulphanilamide products are now issued in 5-g. double envelopes, in addition to 15-g. sealed bottles. This new envelope pack is designed to give full protection to the sterile contents with maximum convenience in use; supplied in packings of 6, 25, and 100 envelopes. The products available are "Wellcome" brand sterilized sulphanilamide (a crystalline powder suitable for all forms of local chemotherapy) and sterilized sulphanilamide compound (a finely divided free-flowing powder containing 5% of zinc oxide, for use on surface lesions and open wounds only). Further particulars may be had from Burroughs Wellcome and Co. 12, Red Lion Square, London, W.C.1.

## BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 4 1944

TREATMENT OF CHRONIC ARTHRITIS  
WITH GOLD

The conspicuous lack of carefully controlled observations on the treatment of rheumatoid arthritis by gold makes the work of Freyburg, Block, and Levy especially welcome. They have made a careful study of the metabolism, toxicity, and mode of action of certain gold preparations, with the stated intention of trying to eliminate some of the vagaries attending this form of treatment. In 1941 they published a report on the first stage of their researches, which was reviewed in this *Journal*.<sup>1</sup> They showed that when gold sodium thiomalate (myocrisin) and gold sodium thiosulphate (sanocrysin), both crystalline salts in aqueous solution, were given intramuscularly, gold appeared in the plasma and urine. Though the larger doses gave high plasma levels, these were not directly proportional to the weekly intake, and it was uncertain whether there was complete absorption from the muscle depots. Excretion by the kidneys was also not proportional to the amount given or the plasma levels, and it never exceeded 1 mg. a week. This led to an increasing retention of gold during the period of administration. Where large doses had been given, as much as 80% remained in the body at the end of a course of injections, and significant amounts of gold were found in the plasma and urine during the next six to twelve months. There was no evidence that the gold was concentrated in the synovial fluid, which contained amounts equal to or less than the amount in the plasma. Five out of six patients treated with weekly doses containing 50 mg. gold had toxic reactions, whereas eight patients given 25 mg. had none. While the findings with myocrisin and sanocrysin were essentially similar and consistent in all subjects, very different results were obtained with colloidal gold sulphide. The plasma and urine levels were much lower than those found with the inorganic salts, and there was considerable individual variation which did not appear to depend on whether the drug was given by mouth or intramuscularly. It was clear that more work was needed to account for the difference between the results with the crystalline and the colloidal preparations; to determine the factors controlling the absorption of the gold and its distribution in the body tissues; and to assess the margin of safety between effective dosage and the development of toxic reactions.

A further report on these researches<sup>2</sup> has clarified some of the points raised in the initial investigation. A comparison between the effects of intravenous and intramuscular injection of the soluble inorganic salts has revealed rapid and complete absorption from the muscle depots. In contrast with this, practically none of the insoluble calcium gold thiomalate was absorbed during the first 24 hours,

and gold thioglucose, injected intramuscularly in oil, was absorbed only slowly and gave plasma values equivalent to two-thirds of those obtained with the salts in aqueous solution. Experiments on animals have shown that the reason for the low values obtained with colloidal gold sulphide is not incomplete absorption of the drug, but the fact that the colloidal particles are taken up in large amounts by the reticulo-endothelial system, especially the liver and spleen. Even when the drug was given intramuscularly, all the gold had left the blood and been phagocytosed in less than one hour.

If gold is to be effective in arthritis it must be given in a form which is easily absorbed and which will remain in the circulation long enough to reach the site where it will exert its action. Dr. Freyburg and his co-workers have shown that such conditions are probably best obtained by intramuscular injections of the water-soluble gold salts. These drugs are potentially toxic and are retained in the body for a long time after the period of administration. As there is no known method of inhibiting the toxic action, which may appear late in the treatment when the patient has large amounts of gold in his system, it is essential to restrict dosage to the smallest amount known to be effective. A detailed study of the optimal dosage has convinced Freyburg that when these crystalline salts are used the equivalent of 25 mg. gold weekly, which in the case of myocrisin is contained in 50 mg. of the salt, is the minimal effective dose, and the total quantity of gold given should not exceed 1 gramme. Using this amount, he claims to have produced results as good as those obtained with 50 mg. gold weekly, and to have lowered the incidence and severity of the toxic reactions. These fell from 41 to 17%, and there were no cases of nephritis, exfoliative dermatitis, or other severe reactions. Smaller doses appeared to be less effective in the treatment of arthritis, and colloidal gold sulphide gave little or no benefit. He concludes that this is due to the fact that gold in this form is immediately phagocytosed and thereby rendered completely ineffective. For the same reason it is unlikely to cause any toxic reactions. Freyburg sums up the present position by saying that so far no dosage of gold can be recommended which is both therapeutically effective and yet below the level of toxicity. This makes it all the more important that only cases likely to obtain benefit should be selected for this treatment, and it is difficult to do this, as it is still unknown where, how, or why gold salts work. Major errors can be avoided if it is realized that the only possible action of gold is to lessen or arrest inflammation. No benefit can be expected in osteo-arthritis, which is a degenerative non-inflammatory joint disease, or in old-standing rheumatoid arthritis with irreversible bone and joint changes. Only patients in the active inflammatory stage of rheumatoid arthritis are suitable candidates for the treatment; and even in them improvement is uncertain, and there is always a risk of toxic complications.

The subject cannot be left without some reference to the recent work of Sabin, though it is still not known how far his results are relevant to human beings.<sup>3</sup> He has induced an experimental arthritis in mice which resembles rheumatoid arthritis in many of its clinical and pathological

<sup>2</sup> *Proc. Mayo Clin.*, 1942, 17, 534.

<sup>3</sup> *Proc. Mayo Clin.*, 1942, 17, 542.

manifestations, and has shown that it can be successfully treated with certain gold salts provided treatment is started within three weeks of the onset of the disease. If treatment is delayed until destruction of cartilage and obliteration of the affected joints have occurred little or no improvement can be expected. To obtain a full cure with no risk of relapse full doses are required, which cause toxic reactions in a large number of mice. He found that the therapeutic effectiveness of gold compounds depended chiefly on the concentration of gold, whereas toxicity depended more on the nature of the radical to which the gold was attached and on the degree of solubility. Colloidal gold was without effect. These ideas led to the discovery of calcium aurothiomalate, which was effective in mice in even smaller dosage than the corresponding sodium salt and much less toxic. This compound is now being tested in man, and it is as yet too early to decide whether it is equally non-toxic in human arthritis, but it is already clear that it can cause dermatitis and stomatitis.

### TRILENE HAZARD

Trichlorethylene (trilene) is a chlorinated hydrocarbon of the aliphatic series, of which chloroform is the best-known representative. It is a colourless liquid with a characteristic smell; when sold as an anaesthetic it is stained blue for the purpose of identification. It has been known in industry for at least thirty years, being used for degreasing metals; in the extraction of oils and fats; in painting, enamelling, dyeing, and dry-cleaning; in the boot and shoe industry; in textile manufacture and the printing industry; as an insecticide, a disinfecting agent, and an impregnation material; in cleaning films, photographic plates, and optical lenses; in the chemical industry; in gas purification; and as a rubber solvent. It differs from other chlorinated hydrocarbons by not producing any severe lesion of the liver or kidneys in experimental animals; only Castellino<sup>1</sup> and Lande<sup>2</sup> have reported any changes. Toxic jaundice has been recorded in man by Bridge<sup>3</sup> and Wilcox,<sup>4</sup> but the evidence for attributing it to trichlorethylene is quite inadequate. Like similar substances, trichlorethylene may produce dermatitis by its solvent action upon the fat in the skin. In industry, however, the chief danger of this substance has been that of acute narcosis following prolonged exposure to high concentrations. Stüber<sup>5</sup> has reported 117 cases of unconsciousness in workers in German factories, of whom twelve died; similar cases have occurred in England, and between 1921 and 1935 thirty-one cases, three of which were fatal, were reported to H.M. Chief Inspector of Factories. This knowledge led Striker, Goldblatt, Warn, and Jackson<sup>6</sup> to use trichlorethylene as an anaesthetic. Hewer and Hadfield,<sup>7</sup> first reporting its use in England, considered that it resembled chloroform in its effect, but was less potent as an anaesthetic, more potent as an analgesic, and less toxic. The advantages of the drug are the absence of

irritation to the respiratory tract, the small amount of oozing from cut tissues, the high degree of analgesia, and its relative cheapness. The disadvantages are the difficulty in obtaining muscular relaxation, its tendency to raise the respiratory rate, and the fact that it is retained for many hours in the blood stream, thus tending to prolong the stage of recovery.

It has never been understood why cranial-nerve palsies have been reported from German industry, and yet no case has ever occurred in Great Britain. As early as 1916 Plessner<sup>8</sup> reported that patients suffering from chronic trichlorethylene poisoning showed complete bilateral paralysis of the fifth nerve; and since then German factory inspectors have described corneal ulcer resulting from a foreign body in the eye, the workman not having been aware of its presence because of an anaesthesia of the cornea. Of Stüber's 284 cases ten showed fifth-nerve paralysis and nine optic disturbances. These included blindness from optic atrophy in two, and retrobulbar neuritis with disturbances of the colour field in the others. Isenschmid and Kunz<sup>9</sup> described the case of a man who, after exposure to the vapour of trichlorethylene in cleaning steel cylinders, developed retrobulbar neuritis, left-sided paralysis of his tongue, and polyneuritis of all four limbs. No evidence has ever been brought forward that any of these toxic manifestations were caused by phosgene, which can theoretically be produced as a breakdown product from trichlorethylene. Oljenick<sup>10</sup> used the drug for the relief of pain in trigeminal neuralgia. The vapour is inhaled from broken capsules as in the case of amyl nitrite; the method was popular for some time, but eventually proved disappointing. Jackson<sup>11</sup> pointed out that no local paralysis resulted from this treatment, and suggested that trigeminal paralysis was due to some other poison and not trichlorethylene. Because of its analgesic properties it has also been used to relieve angina, but again the results have been disappointing.

Cases of trigeminal paralysis following trilene anaesthesia have recently been reported. In this issue of the *Journal* Humphrey and McClelland, and Carden, report a total of seventeen cases in which cranial-nerve palsies, sometimes with herpes, developed after general anaesthesia. In two of the cases reported by Humphrey and McClelland the patient died; and at least four other fatal cases are known to have occurred in different parts of the country. In all of these a closed-circuit apparatus was used, and, despite the fact that thirteen out of fifteen of the cases of Humphrey and McClelland did not have trilene as the anaesthetic, the notorious reputation of trichlorethylene led to its being suspected as the noxious agent. Cox proved that when trichlorethylene is passed over soda-lime dichloroacetylene is formed, and—as Dr. Donald Hunter observes in our correspondence pages—this has been confirmed by Milton and Graham. Humphrey and McClelland have shown that this substance is highly toxic to rabbits. It caused death in convulsions, and histologically gross changes were present in brain, liver, and kidneys. Milton, Graham, Perry, and

Hunter have confirmed these results by similar experiments on rats. It seems probable that the trigeminal anaesthesia in German industry which has been up to now such a mystery must be due to dichloroacetylene either present as an impurity or formed by the close proximity of alkali.

The most important conclusion from these observations, however, is that trilene must never be used in a closed-circuit anaesthetic apparatus. Not only is dichloroacetylene a highly toxic substance and dangerous to the person being anaesthetized, but it is stored in the soda-lime canister and may be volatilized by a later anaesthetic, particularly if ether is used. It may thus have toxic or even fatal results, even though no trilene be used in the subsequent anaesthetic.

### FAMILIAL ANAPHYLACTIC DEATH

Human death from allergic shock is a very rare phenomenon. Yet many medical men with long experience of the administration of antitoxic sera have experienced the tragedy of death occurring within half an hour of the injection, often a small dose, of therapeutic antitoxin. These rare fatal accidents do not happen as a rule in persons who are known to be sensitized by a recent injection of foreign protein: in them the anaphylactic reaction is rare compared with its practically constant occurrence in sensitized animals, and when it occurs in severe form with respiratory distress and widespread oedema it is seldom fatal and responds well to the injection of adrenaline. The fatal case is most often a child or young adult with little or no history to suggest hypersensitivity to foreign protein, though careful questioning afterwards may reveal some personal or familial allergic tendency. This allergic state, usually of a broad non-specific character, either is hereditary or is acquired in early childhood. A case of the kind with an interesting family history has lately been reported.<sup>1</sup> A number of nurses in a mental hospital were being used as volunteer controls in tests to determine the rate of cutaneous colour-spread among schizophrenics. The test substance was a solution of guinea-pig haemoglobin, of which 0.2 c.cm. was injected intradermally. Within 10 minutes of the injection one of the nurses died in acute respiratory distress and cyanosis despite all attempts at resuscitation with intracardiac adrenaline and artificial respiration. At necropsy there was an inflammatory haemorrhagic patch at the site of inoculation, the lungs were distended and emphysematous, and there were marked hyperaemia and oedema of the respiratory mucous membranes. It was, in fact, the typical picture of anaphylactic shock as seen in the guinea-pig, and this violent reaction, due to the clash of antigen with tissue antibody and characterized by acute spasm of smooth muscle (in this case the terminal bronchioles), together with increased capillary permeability, was set off by a small intradermal injection of an unusual foreign protein. For the first time on record<sup>2</sup> the pathologist carried the diagnosis a step further by performing tests of passive anaphylaxis with the patient's serum obtained by cardiac puncture post mortem. Small amounts of the serum were injected into the forearms of three volunteers and guinea-pig haemoglobin applied by scratch 24 hours later; two of the volunteers showed the typical flare and wheal of the Prausnitz-Küstner phenomenon. Although at the time of the test the affected nurse denied having had any allergic disease, the mother revealed

afterwards that the patient had had asthma for 8 years and was sensitive to a variety of foreign antigens, that she herself was subject to asthmatic attacks, a son to urticaria, and a daughter to acne. Moreover, a cousin of the mother had died of allergic shock within 3 minutes of the injection of 10 c.cm. of Behring's antidiphtheritic serum given because she was a contact of a fatal case of diphtheria and had some exudate on her throat. It was the first reported American death from anaphylaxis after the use of diphtheria antitoxin. The fear of such a tragic accident is a great bogey, not so much to the "fever expert" who is giving antitoxin every day but to the practitioner who, knowing of the possibility, however remote, and realizing the adverse effect such an accident might have upon his practice avoids whenever possible the responsibility of injecting antitoxin. One result is that children still die of diphtheria who might be saved if the doctor would give antitoxin as soon as he suspects the disease. The modern refinements in antisera mean that at this early stage of the infection a protective dose can be given in 2 to 3 c.cm. with the minimum of discomfort or subsequent upset to the child.

How are these allergic deaths to be avoided? Certainly not by the practice of giving a preliminary intradermal or subcutaneous injection of 0.2 to 0.5 c.cm. of antitoxin or normal horse serum to act as a desensitizing dose, for experience has shown that even a minimal dose of foreign protein will act as the trigger in a hypersensitive person. Careful inquiry about any personal or familial history of allergic disease—eczema or urticaria, hay-fever or asthma—is the surest way to reveal the hypersensitive state. To test for sensitivity in a doubtful allergic child the scratch and conjunctival reactions, using a 1 in 10 dilution of the animal serum to be injected, are probably safe and reliable. If the intradermal test is used the serum should be diluted 1 in 100. Desensitization of naturally allergic persons is practically impossible, but if serum therapy is essential a degree of temporary desensitization may be brought about by a graduated series of intradermal or subcutaneous injections of antitoxin half-hourly, beginning with 0.1 c.cm. of a 1 in 100 dilution. Adrenaline in a dose of 3 to 5 minims of a 1 in 1,000 dilution must always be kept ready to deal with any untoward reaction.

### THE SCOTT AND UTHWATT REPORTS

To read Blue Books or White Papers is a discipline only to be undertaken by those who have some background of special knowledge. But to read a Penguin Special is a relaxation, and the producers of these little books have been happily inspired to include one which gives a summary of the Scott and Uthwatt reports.<sup>1</sup> These formidable documents—the first concerning the development of rural areas consistently with the maintenance of agriculture, and the second the public control of the use of land—are presented in a digestible form, and the editor, Mr. G. M. Young, who is a historian and has been a civil servant, contributes an introduction. Briefly, the problem is the reconstruction of the country and the town, but this summary with all its readability leaves us in little doubt of the difficulties that have to be faced before that is achieved. There are all the devastated towns to be rebuilt first, and there may be a great shortage of labour and materials. Old slums have to be cleared away and new housing estates provided, and the former slum population cannot be put under an anaesthetic meanwhile. We have in Great Britain some beautifully planned towns—Bath, for example, and Salisbury—

<sup>1</sup> Hunt, E. L., *New Engl. J. Med.*, 1943, 228, 502.

<sup>2</sup> Lund, H., and Hunt, E. L., *Arch. Path.*, 1941, 32, 664.

<sup>1</sup> *Country and Town: A Summary of the Scott and Uthwatt Reports*. A Penguin Special. Penguin Books, Harmondsworth, Middlesex. (9d.)

but the planning was carried out on clear sites and on a small scale, and the same is true of the New Town of Edinburgh. Readers of Disraeli's *Sybil* will recall Wodgate, an industrial territory which grew and prospered in a state of complete anarchy, like a miners' camp in California. There are many Wodgates—the Potteries, the cotton and woollen countries, Clydeside and Tyneside, and London itself. To get London back to what it might have been if this growth had been controlled from the beginning will not be a task for one generation only. The principles of the Scott and Uthwatt reports are that there shall never be any uncontrolled encroachment on food-bearing land, and that the town—that is, the citizens of the town—shall be given power to own the town. We may well envy our descendants, and they perhaps may mingle their pitying recollection of us with some infusion of gratitude because it was in our distressful time that a beginning was made.

### HUMAN BIOSYNTHESIS OF VITAMIN B<sub>1</sub>

It has always been assumed that man, unlike the rat and some ruminants, is unable to synthesize vitamin B<sub>1</sub>, and that he therefore depends entirely on food for his supply of it. Several studies on this vitamin during the last four years do not show very close agreement on the minimal human requirement. Thus signs attributed to vitamin-B<sub>1</sub> deficiency have been noted on daily intakes varying from 0.25 mg. to 0.6 mg. per 1,000 calories of diet.<sup>1-5</sup> There is a discrepancy not only between these figures but also in the time taken to induce deficiency symptoms on an experimental diet poor in vitamin B<sub>1</sub>. Why should one individual show deficiency symptoms on an intake of 0.5 mg. of vitamin B<sub>1</sub> per 1,000 calories daily, while another can do hard physical work and keep well on an intake of only 0.25 mg.? Hitherto studies have been made by giving foods poor in vitamin B<sub>1</sub> to human volunteers. Najjar and Holt,<sup>6</sup> however, appear to be the first to have devised completely synthetic diets in studies on human vitamin deficiency. They gave nine adolescent males a diet of vitamin-free casein, crisco (a vegetable fat), dextrin-maltose, a mineral mixture, and adequate amounts of the known vitamins except B<sub>1</sub>. This was added to the diet in varying amounts, beginning with 1 mg. daily. The daily intake was slowly reduced by 0.1 mg. to 0.2 mg. and kept at this level for months. No deficiency symptoms were observed. Finally vitamin B<sub>1</sub> was omitted from the diet altogether. In the course of three to five weeks there was clear clinical evidence of vitamin-B<sub>1</sub> deficiency in only five out of nine of the subjects. Examination of the stools, however, showed that the five with signs of deficiency had practically no free vitamin B<sub>1</sub> in their stools, whereas the four who remained symptom-free had large quantities in their stools, in spite of a zero intake. The most likely explanation was that intestinal bacteria were synthesizing vitamin B<sub>1</sub> in the large intestine, from which it was absorbed. To obtain direct evidence of this, succinylsulphathiazole (which is bacteriostatic in the intestine) was given to one of the subjects excreting vitamin B<sub>1</sub> in his faeces. In a week the faecal excretion fell from 37 to 52 micrograms daily down to zero and returned to its former value on discontinuance of the drug. Absorption of vitamin B<sub>1</sub> from the large intestine had still to be proved. This was done by administering retention enemas containing vitamin B<sub>1</sub>; a pronounced rise in the urinary excretion of vitamin B<sub>1</sub> was the result.

These observations demonstrate that the biosynthesis of vitamin B<sub>1</sub> can occur in man, and would explain the discrepancies in the human vitamin-B<sub>1</sub> requirements found by different observers. It also raises the question whether man requires an exogenous source of vitamin B<sub>1</sub>. Can he synthesize enough? It may be that the human requirements of B<sub>1</sub> cannot be sustained for an indefinite length of time by bacterial synthesis. This may only operate when the oral intake of the vitamin is low. It is also possible that minute amounts of vitamin B<sub>1</sub> by mouth are needed for the growth of bacteria. Since it is likely that the biosynthesis of vitamin B<sub>1</sub> is affected by diet, as is known in the case of animals, the vitamin-B<sub>1</sub> requirement of man must be considered in terms of particular diets rather than in general. One further point is worthy of emphasis. Sulphonamide drugs can apparently inhibit the biosynthesis of vitamin B<sub>1</sub> in man. This may be of clinical significance in the case of patients treated with such drugs who are on diets poor in vitamin B<sub>1</sub> or whose food intake is restricted.

### NIGHT VISION BY RED LIGHT

In 1897 Breuer and Pertz established the rather academic fact that the fovea of the macula lutea is less sensitive than the paracentral area both to white light and to all colours except red, to which indeed it was more sensitive. These findings have found practical application during the present war. Foveal vision is of course preferable to paracentral vision, since it is so much sharper, and on theoretical grounds foveal vision could be called into play in low intensities of illumination only if the light used was red in colour. In practice, seeing in the dark—i.e., under conditions of low intensity of illumination—is best accomplished by not looking directly at the object: the seeing is done by the paracentral area, with its greater sensitivity to what amount of light is available. D. Y. Solandt and C. H. Best<sup>1</sup> give an account of a fascinating series of experiments with red lights to enable pilots and navigators to use their foveal vision in the relative darkness of low illumination. Red lighting is now used on aircraft instrument panels and in the Royal Navy. Red goggles are a helpful addition, but the goggles must fit well, as a small leak of white light can ruin their effectiveness. The red light used for lighting purposes is of a limited character; on spectrographic examination it must show little or no energy output at a wave-length below 6,000 Å or preferably 6,200 Å. By enabling the use of foveal vision, the period necessary for dark-adaptation becomes reduced. This is an important corollary of the work recorded by Solandt and Best. Under the special conditions of night vision in red light the problem of dark-adaptation of course still persists, and the authors record modifications they incorporated in the Hecht-Shlaer adapter for the carrying out of the necessary tests for dark-adaptation of the fovea to red light.

The Medical Research Council has established a Unit for Research in Human Nutrition as part of its staff organization, and has appointed Dr. B. S. Platt as Director. Temporary accommodation has been provided at the National Hospital for Nervous Diseases, Queen Square, London. Some part of the investigations undertaken by the unit will be directed towards nutrition problems in the Tropics. Among other things Dr. Platt will continue the work, for which he joined the Council's staff in 1938, of co-ordinating a programme of nutritional investigations in the Colonies by arrangement between the Colonial Office and the Council.

# DEHYDROCHOLIN B.D.H.

## *In Liver Insufficiency*

Varying degrees of liver insufficiency are commonly encountered in practice. The patient with sallow complexion, furred tongue, morning nausea, anorexia, headache, discomfort in the region of the liver, lassitude and depression is all too familiar.

Dehydrocholin B.D.H. is the most powerful cholagogue available, and in such cases produces prompt and effective relief of symptoms. In the initial stages Dehydrocholin B.D.H. should be administered by injection, and thereafter treatment is continued by the administration of tablets by mouth until recovery is complete.

Dehydrocholin B.D.H. is available for intravenous injection in ampoules containing a solution of sodium dehydrocholate, and for oral administration in tablets containing dehydrocholic acid.

*Dehydrocholin B.D.H. is issued for injection as a solution containing 20 per cent. sodium dehydrocholate in ampoules of 10 c.c. and for oral administration in tablets each containing 0.25 grm. of dehydrocholic acid.*

TRADE MARK  
**'SVC'**  
 BRAND  
*acetarsol vaginal compound*  
**in leucorrhoea**

In the treatment of leucorrhoea associated with the presence of *T. vaginalis*, formerly so intractable a condition, 'SVC' brand of acetarsol vaginal compound is frequently effective. The product is available in two forms; tablets of elongated shape for insertion containing grains 4 of acetarsol in each and powder for insufflation containing 12.5% of acetarsol. In response to a number of requests the volume of the latter preparation has recently been doubled, the total acetarsol content remaining the same. Vaginal insufflations are contraindicated during pregnancy.

Tablets available in containers of 25 and 100, powder in containers of 6 x 6 Gm.

**PHARMACEUTICAL SPECIALITIES (MAY & BAKER) LIMITED, DAGENHAM**

Extensive clinical investigation of Pethidine Hydrochloride has confirmed its value as an analgesic and anti-spasmodic for the relief of post-operative pain and of pain associated with spasmodic and neurological disorders, for pre-operative medication, and for administration in obstetrics.

Recent experience indicates that the minimum effective dosage is higher than was previously supposed. For convenience in administration, ampoules containing 100 mgm. of Pethidine Hydrochloride in 2 c.c., for intravenous, intramuscular and subcutaneous injection, are now supplied in addition to the present strength of 50 mgm.—by the undermentioned companies, some of which will also issue tablets of 50 mgm. of Pethidine Hydrochloride, in addition to the present 25 mgm. products for oral use.

## WITH THE FRIENDS' AMBULANCE UNIT IN CHINA

### GENERAL PRACTICE AMONG THE HAKKA

by

HANDLEY LAYCOCK, M.B., F.R.C.S.

(Until Recently a Member of the F.A.U., China Section)

War leads us into strange places, and one of the unexpected occupations it has found for me is being in general practice among the Hakka people of South China. At present my life falls into two phases. In one I look after a hospital for Chinese soldiers and refugees in a large and more or less important city, and in the other, as I say, I am in general practice among the Hakka. The fact that the Cantonese language is used in the city and the Hakka language in the country and that I am no linguist is just one of the little difficulties that go to make life really complicated.

Our Hakka out-patients are mixed up with Cantonese soldiers and a motley collection of beggars and refugees. The latter are usually starving, desperate, and all too often truculent in their demands for money, food, and medical attention. They are a ghastly by-product of war and one feels very sorry for them, but the Hakka villagers are more normal and much more reliable.

The process of taking the temperature had always seemed a simple one to me. The Hakka child has shown me that it can be made almost impossible. When he is presented with a thermometer he is apt to do surprising things—to close his mouth and eyes, to arch his back, and sometimes to start sweating as if in terror. When he is persuaded to open his mouth he usually puts his tongue out and refuses to put it in again. Unfortunately at the moment my grasp of the language is such that I can ask for the tongue to be put out but have not yet learnt the correct way of suggesting that it be withdrawn. When he has the idea that the thermometer is to go under the tongue he usually presses the latter firmly against the palate, keeping the mouth wide open. When finally induced to shut his mouth he is apt to bite the instrument in half with a vicious snap. When at last all seems settled, the patient is quite liable to open his mouth and let the thermometer fall out on to the stone floor! So I have planned, but not yet been able to construct, a special device for taking the temperatures of the Hakka people. Practitioners among other simple people may care to copy. The body of the thermometer is protected from bites by a thin brass tube, and the whole is suspended by a short length of chain from a band previously strapped round the forehead.

#### "Simple" Dermatology

Many of the patients have skin troubles. I never fancied myself as a dermatologist, but Hakka dermatology is easy. There are three diagnoses—ringworm, scabies, and ulcers of the leg. The ringworm is not atypical but is sometimes very extensive. We see scabies in its grossest forms, though the worst cases occur among the soldiers rather than the villagers. A man comes to us covered from the neck downwards with scabs like the rupia of late secondary syphilis. Sometimes the whole surface of the body is covered with scales and resembles ichthyosis. I believe these types are simply due to secondarily infected scabies, because their disappearance with sulphur treatment is so rapid and so complete. We can buy crude brimstone, by one of the freaks of wartime economics, at less than the current price by weight of rice, and we mix it with pork fat in large quantities. The sufferers are invited to attend a "scabies clinic" on Tuesday, Wednesday, and Thursday afternoons and to bring clean clothes with them. They have a bath first and are then rubbed all over with our ointment, and the worst cases get better. I have also been surprised to find that some of the ulcers resistant to other forms of treatment begin to do well when sulphur is applied to them. Many of these ulcers undoubtedly start where the lesions of scabies are scratched, and it looks as though the scabies may remain active and prevent the ulcer from healing.

The ulcers themselves are quite remarkable. Some of them would create a major sensation if seen in "casualty" at a London teaching hospital. Most of them would be labelled "gummatous" if shown in the Final Coojoint vivis vocibus. As regards the syphilitic aetiology, we do not have the normal laboratory facilities. Our supplies of organic arsenical preparations are small and they have to be reserved for special cases. When simple antiseptic treatment of the ulcer fails and where relapses occur I have several times seen dramatic results follow a single intravenous injection of neosarphenamine. Varicose veins are relatively uncommon and we do not see the typical "varicose ulcer" so common at home. Most of our cases give a history of trivial trauma: "I struck it with a piece of bamboo"; "I

scratched a mosquito bite"; "I was bitten by a chicken"; and so on. The ulcer is then enlarged, secondarily infected, and prevented from healing by the repeated application of filthy poultices purchased from the village herbalist or concocted according to the recipe of a misguided neighbour. These are usually composed of vegetable matter and resemble stale cow-dung. I believe an enormous number of completely crippling ulcers are caused and maintained in this way alone. In a country where the struggle for existence is always fierce, these ulcers must frequently be the undoing of their unlucky owners.

An ulcer of another type might be called the "beriberi ulcer". It is quite characteristic, and I have seen half a dozen in the last six months. It is roughly rectangular in shape and about 6 in. by 2½ in. on the dorsal aspect of the foot, extending above and behind the lateral malleolus, which sometimes escapes and has an island of intact skin upon it. The ulcer was in one case bilateral. The patient always gives the same history. He had swelling of the feet—beriberi is very common in this district—and applied Chinese medicine in an attempt to cure this. I do not know of what this particular application consists, but it acts like strong caustic soda, and the sufferer comes to us after about a week with a dead white area of skin like chamois leather covering the area described. In a few days this separates, leaving a deep ulcer in which the extensor tendons may be fully exposed. In one case the whole foot had become so grossly infected that I felt obliged to amputate, but the patient, who was much the worse for starvation and septic absorption, did not survive. A case I am treating at the moment has been dressed daily since before the slough separated and has been on a good diet. The ulcer was very large, but with antiseptic dressings (Dakin's solution at first and later acriflavine) secondary infection has been minimized and epithelization is proceeding so rapidly that the skin-grafting which I at first contemplated now seems superfluous.

#### Settling the Bill

Many of the patients to whom we give free treatment bring presents with them—eggs, sweet potatoes, nondescript vegetables, peculiar sodden pink cakes, and so on. Often these are the spontaneous expression of a sincere appreciation for what has been done. One man, from whose upper lip I had removed a peculiar adenomatous tumour, said thank you with fifteen eggs and a plateful of litchis. I soon discovered, however, that in some cases the real significance of the presents was that the sufferer was anxious to give a gentle hint to the doctor to try a little harder. Surely a doctor who had been put under a sense of obligation by receiving a dozen eggs would feel bound to make even more desperate efforts to effect a rapid cure! One old lady with severe corneal opacities for which I could do nothing brought me an embarrassingly large offering of fruit and vegetables, but I persuaded her to take most of them away again.

Sometimes the doctor goes visiting. Passing through a Hakka village he is quickly recognized and a commotion follows. He is besought to come and advise about the local sick. On these occasions one never knows what to expect. The most ghastly spectacle may suddenly be brought out of some dark back room for inspection. Once I found a 16-year-old girl who had had an ulcer for two years. It three-quarters encircled the leg at the middle of the calf and had eaten deeply into the muscles, which were partly gangrenous and stinking. This had been caused by a small injury and prevented from healing in the usual way—the continuous applications of filthy poultices. From chronic toxic absorption the girl appeared almost moribund, was quite unable to stand, was in great pain, as well as being a nuisance to the whole village on account of the smell. We arranged to have her carried in a basket to our dressing room, where I cut away without anaesthesia a large quantity of dead muscle. It was then possible for her to arrange to live near by and to come in daily for dressings. As she is one of our more successful cases, I say boastfully that she now walks unaided, her ulcer is very much smaller—there will always be a contracture of the muscle—she is fatter, and definitely possesses that certain something called "S.A."

The effect of applying microcrystalline sulphonamides to the monkey's brain was examined with the aid of electro-encephalography by H. Jasper and his colleagues (*Surg. Gynec. Obstet.*, 1943, 76, 599). It was observed that sulphathiazole directly applied to the cerebral cortex resulted in convulsions which developed into generalized epileptic seizures. Intravenous injection of sodium sulphathiazole produced convulsions with a concentration of the unconjugated drug of over 80 mg. per 100 c.c.m. When the drug was one-quarter and one-half this amount excitatory effects could be observed in the electro-encephalogram. The local application of sulphanilamide, sulphapyridine, and sulphadiazine to the uninjured cortex was without effect. The authors recommend a combination of sulphanilamide and sulphadiazine for local application to the brain.

## OPHTHALMOLOGICAL RESEARCH AT OXFORD

The Lord Mayor of London gave a luncheon on Feb. 22 at the Mansion House to representatives of industry and public life to meet the Vice-Chancellor of the University of Oxford (Sir David Ross, Provost of Oriel) and the members of its Ophthalmological Research Endowment Committee.

Sir DAVID ROSS said that what Oxford was concerned with to-day was not the task of making tolerable the lot of the blind but that of preventing blindness and, not less, of preventing defects of sight, many of which fell far short of blindness and yet were a grievous affliction and a grievous handicap to usefulness. The number of blind persons in this country was apparently growing, though not sensationally so; in March, 1942, there were 75,306 blind persons in England and Wales, nearly a thousand more than in the previous year. The causes of blindness seemed to be at least keeping pace with the attempts to prevent it; defects of eyesight short of blindness appeared also to be on the increase. The existence of 75,000 blind people in a population of something over forty millions was itself a great evil; but a little probing into the facts of blindness showed that the position was more serious than even this figure indicated, for many years often elapsed between the onset of the disease and its culmination in blindness. In all accidents leading to blindness the difference between the mean age of onset and the mean age of blindness was 3.11 years; in glaucoma it was 2.94 years, in cataract 5.1, in uveitis 12.4, in trachoma 25.58, in myopia 36.24. Many therefore must suffer for years from severe eye disease but die without swelling the numbers of the blind, and still more for many years before they swelled those numbers. How were those great evils to be remedied? Three things were certainly necessary: improvement of the ophthalmic services of the country, education of the public about the care of the eyes, and research. Of the first two of these research was the essential basis, for improvement of the ophthalmic services required the turning out of a larger number of very highly-qualified oculists, and it was one of the missions of a research institute to turn out, as well as original researchers, practising oculists who would bring the latest results of research to bear on the practice of their profession. And for the education of the public also it was essential that those who carried on this education, in schools and elsewhere, should be *au fait* with the latest and best results of research.

## The Need for Co-operation

Such research could be most effectively pursued not in an isolated ophthalmological institute but in a university, where the workers at this subject could be in close contact with workers in kindred subjects. For while specialism was constantly growing it was at the same time being found more and more that specialists in one subject could profit from co-operation with specialists in other subjects. Thus, many defects of eyesight were due to nutritional factors, and so the ophthalmologist must work hand-in-hand with the biochemist. Phenomena of the eye or of eyesight were sometimes the first indication of disease in some quite different part of the body, and so the ophthalmologist must work hand-in-hand with the professors of other branches of medicine. New drugs like the sulphonamides and penicillin, which were so potent in other branches of medicine, had a utility also for diseases of the eye, and so the ophthalmologist must work hand-in-hand with the pharmacologist and the physiologist.

There was another form of co-operation—that between research and industry. It had in recent months been very forcibly impressed upon this country that in its endowment of research it lagged behind some other countries, and that its industry had suffered much thereby. Those who were engaged in industry must know of many spheres in which the eyesight of the workers was a matter of the greatest consequence to the quality of the product. This was clearly so in all precision work. But what was more curious and not so easily recognized was that for certain special kinds of work characteristics of eyesight which would in most respects be a handicap to the worker became a positive advantage. Many workers were put on very fine jobs without any previous attempt to find out whether they were suited to them, and when trained were discovered to be unable to continue the job because of eye-strain. The wastage might have been saved by the application of eye tests before training. Accordingly, it would very often be a great advantage to employer and worker alike if, before the worker undertook a certain kind of work, he were to undergo a thorough examination of his eyesight. That was one way in which an ophthalmological institute could render great benefits both to employers and workers. There was also the question of the lighting of factories. Both physicists and ophthalmologists had applied themselves to this, but the former were apt to concentrate on the quality and intensity of the light, and the latter on the angle of incidence and direction of the rays; the problem would not be solved until both types of scientists

tackled it together. Some of the work of the Ophthalmological Institute at Oxford would be purely scientific, each new problem being suggested by the existing knowledge and experience of the worker, one problem constantly arising from the solution of another. There would also be work, scientific in its character, but practical in its inception and in its aim. Employers would put to the institute some practical question about lighting, or about prevention of accidents to the eye, or about the excessive incidence of eye trouble in some department, and the institute would do its best to give a practical answer to the practical question. And just as theoretical problems often turned out to have a quite unexpected practical bearing, so the solution of a practical problem might often lead to an important theoretical advance.

## ORDER OF ST. JOHN OF JERUSALEM

The following medical promotions in and appointments to the Venerable Order of St. John of Jerusalem have been announced in the *London Gazette* of June 25, 1943, and Jan. 4, 1944, respectively:

*As Knights:* Dr. K. H. Beverley, Lieut.-Col. W. Blackwood, Dr. L. E. Ellis, Capt. A. C. W. Knox. *As Commanders (Brothers):* Capt. F. E. Bendix, Dr. J. A. Carman, Dr. J. C. Glen, Brig. R. M. Gossline, Capt. H. F. J. Norrie, and Capt. R. V. Steele. *As Officers (Brothers):* Dr. E. S. Abraham, Major I. A. Anderson, Major J. H. Banks, Dr. A. B. Barbour, Lieut.-Col. A. E. Campbell, Dr. T. S. Evans, Dr. K. P. Groves, Dr. B. Hart, Dr. H. R. McAlcenan, Dr. C. F. McGuffin, Dr. C. G. Mackay, Col. J. C. Mackenzie, Major G. W. Parry, Dr. R. R. Roger, Dr. N. J. L. Rollason, Col. P. J. Ryan, Dr. A. U. Sheikh, Dr. M. M. Scott, Surg. Rear-Admiral C. P. G. Wakeley, and Lieut.-Col. C. A. Whiffell. *As Officers (Sisters):* Dr. K. Arditt-Brice and Dr. A. M. Pennell. *As Serving Brothers:* Dr. K. V. Adalia, Dr. O. D. Ballinger, Dr. I. H. Beattie, Dr. J. W. Bennett, Dr. W. E. H. Bull, Dr. A. Chaffron, Dr. O. T. J. C. de H. Clayre, Dr. R. V. S. Cooper, Dr. C. P. Cross, Dr. P. T. J. Doss, Dr. D. Downie, Mr. F. H. Edwards, Dr. James Ewins, Dr. C. E. H. Gaier, Dr. D. G. Geefield, Dr. W. A. Hawes, Dr. G. E. Hayward, Dr. F. L. Heap, Dr. F. W. Hebblethwaite, Dr. L. W. Heffernan, Dr. W. A. Hogg, Dr. A. G. Holman, Dr. J. L. Holt, Dr. J. S. Hutchison, Dr. J. M. Johnstone, Dr. T. P. Lalonde, Dr. J. P. Little, Dr. K. M. Macdonald, Dr. A. D. McQueen, Dr. D. J. Martin, Dr. F. C. Mathew, Dr. S. R. Matthews, Dr. R. W. L. May, Dr. D. McF. Millar, Dr. J. Pirie, Dr. G. H. Pitt, Dr. C. P. Porter, Dr. J. D. Robertson, Dr. H. G. Robinson, Dr. Marshall Robinson, Dr. N. A. Rymor, Dr. H. M. Savory, Dr. R. Scott-Reld, Dr. N. L. Tweedie, Dr. C. A. Wiles, Dr. H. C. Worth, and Lieut.-Col. A. H. O. Young. *As Associate Serving Brothers:* Dr. S. C. Biswas and Capt. D. P. Nath. *As Serving Sisters:* Dr. Millicent Fox, Dr. E. W. Lee, Dr. M. M. Silho, Dr. H. Standring, and Margaret, Lady Ramsden.

*As Knights:* Dr. H. A. Beatty, Major-General S. R. Burston, Dr. T. H. Goddard, and Col. J. A. H. Sherwin. *As Commanders (Brothers):* Lieut.-Col. O. A. Cannon, Dr. A. W. D. Mobbs, Lieut.-Col. F. O'Neill, and Dr. J. Rodley. *As Commander (Sister):* Dame Louise Mellroy, M.D. *As Officers (Brothers):* Lieut.-Col. C. G. Booker, Dr. W. N. Brennen, Dr. L. J. Dunstone, Lieut.-Col. G. D. English, Capt. A. E. E. Grounds, Dr. C. N. Groves, Major L. Haden Guest, Lieut.-Col. G. P. Howlett, Dr. E. M. Humphrey, Dr. M. J. Kelly, Lieut.-Col. D. S. Mackay (since deceased), Dr. H. A. Matheson, Dr. D. McF. Millar, Dr. A. R. Morton, Dr. J. E. O'Donnell, Dr. Rupert Palmer, Dr. W. E. Peck, Dr. R. R. Scott, and Dr. F. W. Vint. *As Serving Brothers:* Dr. J. B. Adamson, Dr. F. H. Alexander, Dr. H. C. Altwood, Dr. W. S. Booth, Dr. A. C. Brown, Dr. H. S. Brown, Col. A. L. Buchanan, Dr. A. Byrne-Quinn, Dr. P. T. Cairns, Dr. R. Chester, Major H. Davenport, Dr. L. S. Debenham, Lieut.-Col. C. G. L. van Dyk, Dr. W. S. Ghal, Lieut.-Col. H. M. Jamieson, Dr. J. F. Jarvis, Dr. S. H. Keshen, Dr. J. W. Mackay, Dr. H. N. Middleton, Dr. R. T. E. Naismith, Dr. T. J. Nicholl, Dr. B. Sweeten, Major L. G. Tassie, Dr. R. Tudor-Edwards, Dr. C. W. Walker, Dr. Arthur Walson, Capt. E. M. B. West, and Dr. R. N. P. Wilton. *As Associate Serving Brothers:* Dr. B. Gopal, Dr. J. V. Reuben, and Capt. N. J. Vazifdar. *As Serving Sisters:* Dr. Gwendolen M. Brown, Dr. G. A. Dancy, and Dr. G. M. B. Totland.

The Organization of a Hospital Rehabilitation Department is the title of E.M.S. Memorandum No. 6 recently issued by the Ministry of Health. While the memorandum recognizes that each hospital must be left to consider the scheme best suited to its own particular problems, it nevertheless outlines a general programme, lists the various procedures commonly employed at different stages of rehabilitation, and indicates the facilities—equipment as well as personnel—essential to carrying out this programme. The Ministry states that it is desirable that all these activities should be under the personal supervision of one member of the medical staff. This, it is held, in no sense interferes with the continuity of control exercised over the individual patient by the original physician, surgeon, or obstetrician who orders rehabilitation treatment and with whom the medical supervisor will work in close association. The memorandum includes details of courses on rehabilitation arranged by the Ministry of Health; for instance, week-end courses for doctors are held from time to time at certain selected centres, where lectures and demonstrations are given by experts. Full particulars of these can be obtained from the Regional or Sector Hospital Officer. The memorandum itself can be obtained through any bookseller or from H.M. Stationery Office (2d.).

## Correspondence

### India's Population Problem

SIR,—Prof. Blacklock's reasoned statement of the problem of population and food supply in India has had a reception which is strikingly reminiscent of that accorded to Mr. Churchill's pre-war efforts to arouse us to a sense of the dangers that threatened this country. The critics of Prof. Blacklock's paper have seized the opportunity of repeating the parrot cry, "Malthus has been discredited." Obviously they have never read what Malthus wrote; his great "principle," briefly and largely in his own words, was that in man as in other animals there is a universal tendency for population to out-run food supply, so that the checks imposed by famine, war, pestilence, misery, and vice must continue to maintain the balance unless preventive checks in the form of delayed marriage, celibacy, and sexual restraint are applied. The teaching of Malthus has been completely misrepresented by persons who were ignorant of the proviso, which is an essential part of the doctrine. The above methods of birth control advocated by Malthus, and others which he would have condemned, have been applied so thoroughly in this country that if he were alive to-day he would be as outspoken in the denunciation of race suicide as he was in advocating the application of the checks which he grouped under the term "moral restraint." As Guillebrand has pointed out, the "principle" of Malthus still seems to reign supreme in the East.

The critics have said little about the hard facts of the situation in India, but at least two of them have made grossly misleading statements regarding the outstanding fact, which is the growth of population. One of them stated that this was by only 18.9% in 50 years. The census figures show an increase of 10.6% from 1921 to 1931, and a further increase of 15% in the next ten years. The increase in the past 25 years must, therefore, have been more than 30%. The actual increase between 1931 and 1941 was 50 millions.

Other facts are as follows: the recent famine in Bengal, where the population had risen from 50 millions in 1931 to 60 millions in 1941; the fact that girls in India begin to cohabit with their husbands at the average age of about 14, and give birth to their first baby at the average age of about 16; these estimates are based on the replies of 571 Indian doctors in rural areas to a questionnaire issued by me in 1931. Among the replies to other fact-finding questions is one in which the same doctors estimated that 60% of the people in their villages were either "poorly" or "very badly" nourished. This percentage would have been much higher if it were not that far lower standards of nutrition are regarded as normal in India than in this country. The only other fact that need be mentioned is the average duration of life in India; this is about half what it ought to be. The explanation of these facts will be clear to anyone who stops to think what conditions in England would be to-day if Oriental marriage customs had prevailed during the past hundred years, and if there had been no outlet in the shape of large-scale emigration.

Although the critics have belittled the gravity of the situation they have offered certain remedies. One of them points out that India could produce more than four times as much food as she does at present. Even if this fantastically optimistic estimate were accepted, it must be clear that people cannot be fed on what might, could, would, or should be produced but only on what can, and will, be produced. Another interesting remedy is suggested—namely, that in accordance with the terms of the Atlantic Charter an ample supply of food should be brought in from outside; the resultant freedom from want would promptly check the potential fertility of the people. The same remedy would have to be applied to China and other over-populated countries, so that this remarkable biological experiment would make heavy demands on the resources and on the altruism of the rest of the world. There is so little chance of the carrying out of this experiment that there is no need to speculate about what would happen if the natural fertility were not checked and if the survival rate were greatly increased.

Complete independence for India is another remedy; this has the great advantage that it will soon be available, but none of the aspirants to the political control of India has given any hint of the existence of a plan for dealing with the baffling problem, and although the Provinces, which have been autonomous for several years, have made commendable efforts in promoting medical relief and public health, none of them has shown signs of attacking the root of the trouble any more than did the British administration which was formerly in charge.

In view of the disquieting facts already mentioned the question will naturally be asked: What have medical men in India been doing to cope with the problem? One example of their action is that the medical research workers at four successive annual conferences from 1923 onwards unanimously adopted resolutions proposed by myself in which they pointed out that India was in a state of grave emergency, and they made an urgent appeal to Government to appoint a strong commission, chiefly non-technical, to investigate the causes of the wastage of life and the economic depression from which India was suffering. Similar representations have been made from time to time, but evidently those who expressed anxiety about the existing conditions and the future prospects of India were regarded as alarmists. At last an investigation has been started under the chairmanship of Sir Joseph Bhore, who is not likely to find the situation so satisfactory as some of Prof. Blacklock's critics seem to do.

The solution of the problem is easy to find: it lies in increasing the production of food and in regulating the rate of reproduction of children so as to maintain a satisfactory balance between food supply and population. It is in the application of the remedy that appalling difficulties will be encountered. There are many who believe that the people of India will never be prepared to make the necessary changes in their social customs. On the other hand, several educated Indians have assured me that if the people can be shown how to improve their conditions of life they will not allow religious or other prejudices to stand in their way. This, however, is a matter for Indians themselves to deal with; they will properly resent any dictation from outside. One thing is clear: most of the educated Indians welcome a frank discussion of the problem and take a more realistic view of the situation than Europeans seem to think.

The following tragi-comic incident related by Lieut.-Col. G. Waters in his privately published *Reminiscences* illustrates this point and shows that the population problem is not a recent development. During a period of famine, about 1875, the Minister of a South Mahratta State read an address to Sir Richard Temple, Governor of Bombay, "praying him to use his high character and transcendent ability to restrain, in some measure at all events, the inordinate aptitude of the people to increase the population." The Governor was very indignant and protested that he "would do everything in his power for the increase, and nothing for the diminution, of the number of Her Majesty's subjects." The Minister and his friends were amazed that His Excellency should have taken offence at so reasonable a request.—I am, etc.,

Hawkhurst, Kent

### Nursery Schools and Classes for Young Children

SIR,—In view of the Education Bill the Executive Committee of the Medical Women's Federation wishes to draw attention to points connected with the provision of nursery schools and classes for children under the age of 5 years. As a result of reports from doctors having personal experience of the care of young children in many different districts of England, Scotland, and Wales, it has become evident that great importance must be given to the following considerations:

1. It is generally agreed that children between the ages of 3 and 5 years benefit from some form of community life, but serious doubt is felt as to the advisability of making extensive provision for children under the age of 3 years.

2. A nursery school forms a suitable environment for the majority of children in the 3-5-year-old age group provided: (a) that it is an independent unit with proper safeguards for the health of the children; (b) that the responsible staff have had special training and experience in the handling of these children both from the mental and physical aspects, and have

also had a grounding in practical hygiene; (c) that emphasis is laid on the fact that up to the age of 5 years the main consideration is health of mind and body, and that to ensure adequate health supervision there must be the closest co-operation between the nursery school and the various health services—i.e., child welfare centres, health visitors, school nurses, and doctors.

The nursery school can satisfy these desiderata, but we would deprecate any scheme of nursery classes. In these it is very doubtful that the right emphasis can always be secured, the class being a subsidiary element in the whole primary school in which the main interest must of necessity be centred on education rather than on health.—I am, etc.,

JANET K. AITKEN,  
President, Medical Women's Federation.

### Babies in Glass Cages

SIR,—To understand the reason for the new infant wards at the Birmingham Children's Hospital, Dr. H. C. Scott need only read the first sentence of the letter which immediately followed his in your issue of Feb. 19. This is, "I am in complete agreement with Dr. Margaret Dunstan in her opinion that under present conditions it is dangerous to admit infants into hospital." For many years it was my practice to admit infants into "open wards," and I have only too often proved the truth of that statement—an experience shared by every paediatrician. On the other hand, in the two to three years during which our new wards have been in use, I have had convincing evidence that our technique, if rigidly carried out, removes much of that danger and saves the lives of many infants. Am I right in assuming that because of what he considers "the ultimate consequences to mental health" of this treatment Dr. Scott would prefer that these children should die? As a matter of fact, he has not a shred of evidence of the results, good or bad, upon their mental health.

The journalistic interest in this experiment is the result of the Charles West Lecture recently delivered by me before the Royal College of Physicians. In that lecture I pointed out that the common infections from which young infants suffered were those affecting the gastro-intestinal and respiratory tracts; surgical sepsis, which Dr. Scott appears to think is the commonest form of infection, is an insignificant factor in infantile and neonatal morbidity and mortality.

Dr. Scott's description of the lives of these infants while in hospital is purely hypothetical, and to answer all his points would make this letter too long. I would, however, give him a cordial invitation to visit Birmingham and see how the system works. He would then not only be in a better position to criticize or praise but would find that the babies are given that "mothering" which is so essential either by their mothers or by a group of devoted nurses who strongly resent the suggestion that their work is "barely humane." Finally, a perusal of Prof. Garrod's paper on "Light as a Hygienic Safeguard," which appears in the same issue of the *Journal* as Dr. Scott's letter, might persuade him that there is something to be said for an extensive use of glass in hospital wards.—I am, etc.,

Birmingham

LEONARD G. PARSONS.

### Rehabilitation: Its Terms of Reference

SIR,—Dr. Jeaffreson Lloyd's letter on rehabilitation (Feb. 19, p. 264) is a refreshing commentary on a subject which, in its concept and connotation alike, has been accepted uncritically. There seems to be a grave danger of losing sight of the end to which it is designed, of mistaking the gymnasium for the factory, an artificial crowd of potential litigants for the normally integrated industrial community. Only in the factory can full psychosomatic readaptation be accomplished in the sense of restoring the human organism to its biological environment. The word "rehabilitation" itself has often been found difficult, even for a county court judge to pronounce, and for that reason alone should be abolished. But more important still is the suspicion that those who first made use of the term in its modern application were more technically than philosophically minded, and their chief concern was with the restitution of *habilitas* instead of regregation, the return to the *grex*.

Why is rehabilitation always confined to those surgical cases of occupational origin? True, we are about to witness the inception of an institution for the rehabilitation of the neurotic workmen, but what of the tuberculous, the psychotic, the dys-

peptic, the cardiac, the silicotic, and the ataxic? We must not deny occupational therapy to these; society must be prepared to receive back all its casualties, whole as well as maimed. All factories should, in proportion to their size and capabilities, aid in the re-education of those muscles and joints and the reorientation of those mental and moral attributes which enable a man to earn his living and take his place in the community. Larger units might find it necessary to create special departments with special conditions of administration, hygiene, and safety. Effective medical supervision for grading and nutrition would, of course, be indispensable.

Francis Galton defined energy as the capacity for labour, as the measure of the fullness of life, and in the darkness of his pre-Freudian mind conceived of fleas instead of libido. Of idle moments in animals he says that "in those blank times there is little for them to attend to besides their varied cutaneous irritations." Scientific advance in another field has given us benzyl benzoate, with the result that we have not even left our casualties anything to scratch, no stimulus to their atrophied muscles and no content to their blank minds. A new and wholly scientific national medical service might conceivably produce impressive therapeutic results and yet leave the gregarious instincts of the sick person unsatisfied. Like the ox of Damara who wanders from the herd "his glance is restless and anxious and is turned in succession to different quarters; his movements are hurried and agitated and he becomes a prey to the extremest terror." Human beings in like circumstances have an unfortunate predilection for looking inwards.

Rehabilitation, as at present understood, will, if unchecked, fall into the pre-Raphaelite error of attempting to solve an industrial problem by altering its terms of reference. The satisfaction of a native reaction tendency in creative art cannot be applied to the processing of materials. Otherwise, the result is something like William Morris's chairs, which pleased the aesthetic sense but to which no one could comfortably approximate his glutei. In other words, while the constructive instinct is of importance in modern industrial life, the gregarious instinct is more manifest. Everyone who is not moribund can and should work, but his capacity to do so and the salvation of his *quintessence* depends upon his spiritual environment. The answer to overproduction is the realization that an abundance of goods is an abundance of wealth, and that for the one to become the other requires the substitution of the human intellect for that of the fox among the hens.

Amnesia bought at a cost of thirty pieces of silver is not only betrayal of the victim but has pathological repercussions in the life of the community, such as political amblyopia, motor anaesthesia, and production palsies. True rehabilitation, therefore, is the essence of "positive health." Any scheme for a national medical service which ignores it in its wider implications will only perpetuate the custom of placating the blind and festering gods of human misfortune with 8-oz. bottles of libations. Meanwhile the vision glorious which has been vouchsafed to this generation will become a cold and pallid Platonic abstraction.—I am, etc.,

Dagenham.

H. WYERS.

### Methionine and Casein Digests in Liver Dysfunction

SIR,—There is a growing body of evidence from careful experimental work on animals to suggest that methionine and casein digests may be valuable therapeutic agents in diseases of the liver, and proof of similar action in man will be most helpful. Some of the opinions advanced by Prof. Beattie and his co-workers in their interesting article on carbon tetrachloride poisoning (Feb. 12, p. 209) are, however, contestable. They give four reasons for their opinion that their patient would probably have died had he not been treated with methionine and casein digest.

1. The large size of the dose (30 to 40 ml.). It is true that this is much larger than the therapeutic dose, and that deaths have occurred with smaller amounts, but there are cases on record in which survival has followed much larger doses. In 1935 Lehnher reported a patient who recovered after swallowing between 140 and 150 ml.

2. There was no vomiting until 45 minutes after swallowing. From this it is assumed that the poison had been completely absorbed. In Lehnher's case, however, vomiting was postponed for 3 hours.

MARCH 4, 1944

## CORRESPONDENCE

BRITISH  
MEDICAL JOURNAL

3. The speed with which the liver enlarged. In a recent investigation of "chronic" carbon tetrachloride poisoning<sup>1</sup> the certifying surgeon responsible for routine examination of the workers noticed that one man had gross enlargement of the liver during a bout of diarrhoea and vomiting that followed exposure to the poison. The finding was confirmed on admission to hospital, where the liver rapidly returned to its normal size and the patient recovered without ever developing jaundice.

4. The delay of 19 hours between the accident and the institution of treatment. Both the cases cited above had no specific treatment. Thus the patient might well have recovered without the help of methionine and casein digest.

Prof. Beattie and his colleagues suppose methionine to have been effective because they believe that "the liver disturbance induced by carbon tetrachloride is an abnormal metabolism of methionine and related compounds." It is not at once clear from the biochemical data how they reach this belief. They appear to base it on a small transient negative nitrogen balance and a "failure to excrete the major portion of the methionine sulphur as oxidized sulphur within 24 hours." It is probably unfair to assume that renal function is unaffected in a case of carbon tetrachloride poisoning, and a temporary derangement may have influenced the nitrogen and sulphur excretion in their case. In addition the negative nitrogen balance may have been due to the very low protein intake during the first two days (Oct. 2 and 3) and to the fever on Oct. 3. The diuresis observed on the days following the methionine administration may also have complicated the study of the nitrogen balance, as a diuresis tends to sweep non-protein nitrogen from the blood stream into the urine. That this may have occurred in their patient is suggested by the fact that there was no change in level of the non-protein nitrogen in the blood despite the fact that the blood amino-acid rose to 12.7 mg./100 ml. on Oct. 3.—We are, etc.,

ALICE STEWART.  
J. P. O'BRIEN.

## Penicillin or Cyllin?

SIR.—In your columns attention has been drawn frequently to the merits of the new remedial agent penicillin. That with it we are better able to combat certain inflammatory conditions cannot be denied. Unfortunately, however, it is impossible yet to obtain it for the treatment of all the cases for which experiment suggests it might be helpful, and its difficulty in preparation makes it an expensive treatment.

After carefully reading the literature in this and other medical journals I am impressed by the fact that for local application to many of the conditions penicillin offers no advantages over cyllin. This is a coal-tar derivative whose effective agent may well have been laid down during the disintegration of its vegetable antecedents. It is miscible in water in all proportions, it does not coagulate proteins, consequently does not produce the superficial necrosis which has been noted in the local application of penicillin and other expensive preparations. It is non-corrosive. It is absorbed to a beneficial extent through the intact skin and is a most effective skin disinfectant. It has a Rideal-Walker coefficient of 18-24. It is cheap and easily obtained. Respecting the latter I would refer to your leading article on skin disinfection (Feb. 5, 1944, p. 188) where it states, "Tests by this laborious method award first prize to tincture of iodine followed by alcohol, and second to alcohol . . . And let it be observed that iodine and spirit are both in very short supply in this country at present; we are in fact asked not to use either when anything else will serve." The preparation of the skin for surgery by thorough cleansing with 4 teaspoonfuls of cyllin to a quart of water will ensure freedom from sepsis. I have used it successfully for many years when there was a liability to skin injury while handling grossly infected material and for the cleansing of wounds sustained during such activities. Used in the water in this proportion for the thorough cleansing of earth-soiled abraded surfaces of the ragged wound, using it in a jet from a large syringe or an elevated douche-can for washing out the deep recesses, will also prevent sepsis. I should regard it as ideal for the cleansing of war wounds.

Distinct from many of the preparations used, because it does not coagulate proteins, it can disinfect material beneath the

surface and prevent the development of sepsis. It is well known as an efficient disinfectant for infected stools. Even when used neat it is not a corrosive.

The proof that it can be absorbed by the skin and used in the treatment of underlying sepsis can readily be obtained by rubbing the neat fluid into the skin over recently infected hair follicles or the early boil. The focus loses its pain and tenderness, the swelling gradually diminishes, and the lesion fades away. I have found it particularly useful in the treatment of early boils at the back of the neck, in the lower nares, and in the external ear. Though the neat fluid or cyllin in olive oil does not burn or cause sensation, the application of water to the surfaces treated will cause a slight burning sensation followed by a localized erythema, but nothing more. Used neat under the nail at the site of an early septic focus it will abolish the pain and throbbing and abort the sepsis. When the lesions have progressed beyond this I have found that repeated immersion of the infected finger in a hot solution of 1 teaspoonful to a quart of water during the day with applications of hot fomentations for the night, using a similar strength, have removed the necessity for surgical intervention. Used locally in this strength, as suggested for penicillin in the septic focus which has been opened, I should expect it to be equally efficacious. Some time ago I saw its cruder preparation used for washing out the uterus of a cow, under conditions of gross infection, from which an impacted full-term calf had been removed bit by bit after multiple insertions of the hand to fix a rope for extraction and for manipulating the wire saw. No indication of sepsis followed, and the cow made an uneventful recovery and exhibited little difference to normal parturition.

Patients referred to me for x-radiation treatment of staphylococcal skin infections of the beard area and other hairy surfaces I have instructed to keep the area clean by the use of 1 teaspoonful of cyllin to each quart of all washing water, and the constant excellent response has always appeared to me to be better than I have found in so short a time when x-radiation alone was given. Infected mucous surfaces as in balanitis respond equally readily to similar treatment. With so effective, harmless, and cheap a preparation would it not be reasonable to use it instead of the expensive penicillin, sulphanilamide, sulphathiazole, alcohol, and such-like preparations for the cleansing and treatment of the skin and its wounds?—I am, etc.,

Birmingham.

JAMES F. BRAILSFORD.

## Teaching of Anaesthetics

SIR.—In spite of great progress in technique and in diminution of patients' discomfort, anaesthetics to-day have two important defects that must be remedied: they are the persistent mortality rate and ineffective teaching. Can anyone doubt that the former is largely due to the latter? Most true anaesthetic fatalities are, as Hewitt insisted years ago, preventable. They happen therefore mostly, not at the hands of those who give most anaesthetics—the experts—but at the hands of those who give fewest—the occasional anaesthetists.

As things are, and probably as they will long be, many anaesthetics all over the country must be given by the occasional anaesthetist. There are not nearly enough experts to go round. It is the business of the medical schools to make this occasional anaesthetist—the general practitioner—a safe administrator. At the present time he is less likely to be so than he was thirty years ago. This is no fault of the teaching anaesthetist. If he does his best for the surgeon and the patient in the theatre he cannot teach the student anything that will help him as an occasional anaesthetist. For this purpose he must be made safe and reasonably competent with the simple methods which alone will be at his disposal.

One suggested solution of the problem is that the student should be much more than at present taught in the casualty operating rooms and in the dental departments. This might certainly help, but the great need, it seems to me, is that the present serious and disappointing state of affairs should be effectually brought to the notice of the medical school committees in all our great schools. They would not, I believe, sit down under the reproach which can now be levelled against them if they fully appreciate its existence.—I am, etc.,

Isleworth.

J. BLOMFELD.

## V.D. and Professional Secrecy

SIR,—With reference to the article entitled "The Modern Treatment of Gonorrhoea in the Female" which appeared under my name in the *British Medical Journal* (Jan. 8, p. 51), there appears to be some doubt as to whether, in the case of a girl under 21, it is always justifiable to tell the parents. Naturally, of course, the consent of the girl should be obtained if possible, but if it is refused it may be that disclosure to the parents would be a breach of professional confidence.

It is generally agreed that a girl living with her parents is under their control, provided she is under 21; where, however, she is living away from them and/or is 18 years old or more and capable of understanding the implications of the disease from which she is suffering, the doctor should, it appears, not communicate the fact that she is suffering from V.D. to the parents against her wishes.

Much, of course, depends on the circumstances of the case, and that is why in my original article I used the words, "In the case of a girl under 21 the parents should be told if the circumstances demand it"; what I had in mind, more especially, was the young girl who is promiscuous and who is in need of care and attention.

I am not a legal expert and should be very glad to hear the opinions of those who are.—I am, etc.,

The War Office, London, S W 1

T. E. OSMOND.

Our Medico-Legal Correspondent writes: In law a person under 21 is not legally competent, and can only sue or be sued in the name of his next friend—usually the parent or guardian. Although a minor could sue a parent in a proper case, in the case supposed by Brigadier Osmond the father is presumably the legal guardian of the girl and would have a right to know any facts on which he ought to take action in the girl's own interest. Therefore the doctor would probably not be breaking any duty owed to the girl if he disclosed her condition to her parents. The whole question of what, if any, duty of secrecy a doctor owes to a patient is quite obscure, and the doctor had far better be guided by his professional conscience. If he does so he is not likely to fall into any legal difficulty. Perhaps the basic question here is, "Would disclosure to the parents be in the best interests of the girl?"

## Regulation 33B

SIR,—Your leading article on Regulation 33B (Feb. 12, p. 223) was, I thought, disappointing. It tended to dismiss the complaints of the voluntary workers who operate it and should know, and was concerned to make excuses for the regulation itself, ignoring the main issue—the treatment of all V.D. cases.

The futility of the regulation you have adequately pointed out: "The number of patients and contacts affected by the regulation is still lamentably small." Of course it is, and it will continue to be so until we make up our minds to grasp the nettle firmly and produce a regulation which will bring V.D. into line with other diseases that are considered sufficiently a public menace as to make them notifiable. The reason for the failure of 33B will be obvious to anyone who has worked in a treatment centre. Patients are, of course, questioned as to the source of infection, and it is rare indeed for a man to admit to any precise knowledge, although women are sometimes more outspoken; the most one can get is a vague promise that the suspected consort will be urged to come up for investigation. So, in the absence of any record of the identities of infecting consorts, how can it be possible, except in rare instances, to apply Regulation 33B to any of the large number of untreated carriers?

If we are honestly concerned about V.D. it should at once be made an offence to have the disease untreated. This would provide for two types of notification: in the first place a private one to the doctor or clinic, thus preserving the present confidential nature of the service; in the second, a public one to the medical officer of health in the case of the recalcitrant and neglectful. This course has the added advantage that private doctors would have to make a return of the numbers they treat, thus giving a much more exact figure of incidence. Further, it would enable us to deal, among others, with the large class who default while still uncured—the husband who

infects his wife while refusing treatment for himself, and those parents who refuse or neglect to have children treated who are congenitally or accidentally infected. The threat of publicity and penalty would bring for investigation large numbers whose consciences, in spite of lack of definite symptoms, are not quite easy; recent propaganda has certainly had its effect, but it does not touch the "don't care" and "it can't happen to me" classes of carrier.—I am, etc.,

London, W. I.

KEITH DUFF, F.R.C.S.

SIR,—Your leading article (Feb. 12, p. 223) deals with Regulation 33B in practice and deplores criticism by lawyers and voluntary workers on the ground that it is unreasonable, although it admits that the criticism that the regulation covers such a minute class that it is practically ineffective is "more reasonable."

In this connexion my committee notes with interest that the objections raised against Regulation 33B by this association when it was introduced in November, 1942, have been justified not only by the criticisms of lawyers and voluntary workers but by the latest statement on the working of the regulation by the Minister of Health in the House of Commons on Feb. 4. He reports that 213 men and 3,131 women had been reported as alleged sources of infection by persons under treatment for V.D. Of this total, 200 men and 2,907 women were the subject of one report only, leaving a total of 4 men and 224 women who were presumably the subject of the two (or more) reports needed to bring them within the scope of Regulation 33B. But of this total of 228 persons only 2 men and 150 women have been brought (compulsorily or voluntarily) under treatment, leaving a balance of 2 men and 74 women who have for some reason evaded treatment. A few women have been imprisoned or fined; a number, according to the Minister, are persons who cannot be traced. Are the remainder uninfected persons who have been victims of careless or malicious accusations?

In any case it is obvious that Regulation 33B does not facilitate to any appreciable degree the tracing of contacts. The majority of these who have been brought under treatment have been reached by the usual methods employed by doctors and workers in any efficiently run clinics long before the introduction of Regulation 33B.

The article, while deploring the lack of results, confronts the legal and medical critics of Regulation 33B with the argument that it must be accepted because it belongs to a class of law hitherto unknown in this country—that is, "administrative law"—which has come to stay. Actually there is growing criticism, both in the House of Commons and the country, of this type of legislation. There is no indication that it will be accepted with complacent acquiescence as a permanent part of our legislative system. The late Lord Chief Justice Hewart was acutely apprehensive of this growing danger to the ordinary citizen, and foretold "the formidable consequences" which inevitably result when Government Departments place themselves "above the sovereignty of Parliament and beyond the jurisdiction of the courts" (*The New Despotism*, 1929). There are signs that this warning from a great lawyer has not fallen on deaf ears.—I am, etc.,

E. M. TURNER.

London, S W 1 Secretary, Association for Moral and Social Hygiene

## Vaginal Ulceration and Vitamin C Deficiency

SIR,—I was interested in the article on this subject by Drs. Lawlor and Richardson (Feb. 19, p. 254). In their discussion of the two cases cited they said smears and cultures revealed no evidence of gonococcal or treponema infection, but they did not indicate whether or not they had excluded the presence of *Oidium albicans* of thrush or *Trichomonas vaginalis*, the latter of which I found to be present in 148 out of a series of 408 consecutive patients complaining of vaginal discharge at the Simpson Maternity Pavilion of the Royal Infirmary, Edinburgh, and who exhibited punctate haemorrhagic spots of the vagina and introitus with irritation.

A cure in these cases, showing absence of the parasite, was associated with reappearance of Döderlein bacilli and of the normal amount of deposition of glycogen in the epithelial cells, together with a return of the pH from between 5 and 6 to the normal pH of the vagina of between 3.8 and 4, as demonstrated by Liston (*Brit. J. vener. Dis.*, 1940, 16, 113).

It may be that deficiency of vitamin C causes alteration in these normal conditions of the vagina which would allow of the growth and development of such a parasite. Investigation of this might prove useful owing to the intractable nature of such an infection.—I am, etc.,

### Induction of Labour by Separation of Membranes

SIR.—The memorandum by Mr. D. Chalmers Wiseman (Feb. 12, p. 221) concerning induction of labour by digital separation of membranes contains, I think, too many controversial statements, put forward as facts, to be allowed to pass unchallenged. To deal with them as they occur:

1. "Caesarean section . . . limits the number of pregnancies to three." This is definitely not so with the lower segment operation. I have seen a patient have her fifth, and have personally carried out a third without sterilization.

2. "Surgical induction by rupturing the hind-waters contraindicates Caesarean section." With careful technique and the use of Drew Smythe's catheter, this is not so. I have several times carried out Caesarean section after this induction, with neither qualms nor untoward results. Surely this operation was devised so as not to rule out subsequent Caesarean section?

3. "In cases of pelvic contraction in which bimanual examination is being carried out at weekly intervals . . ." Is this a common practice? Surely once, or occasionally twice, is sufficient. If there is as much doubt as all this, is not x-ray pelvimetry strongly indicated?

4. "Medical induction is started the same day." Which induction has in fact induced labour—medical or separation of the membranes?

5. ". . . Labour failed to come on within a period of ten days in only three." If Mr. Wiseman allows ten days' grace he will return good figures with almost any method of induction. I consider an induction has failed if labour does not commence within seventy-two hours.

Lastly, I am not decrying separation of the membranes. I employ it along with Drew Smythe's catheter in all cases when the dilatation of the cervix permits.—I am, etc.,

Stockport

WALTER CALVERT

### Heroin and Pethidine during Labour

SIR.—I was much interested in the letter of Dr. James Ross (Jan. 8, p. 59) on the use of heroin in labour, and the two recent articles on pethidine as an obstetric analgesic (Feb. 5). I have recently been using either heroin or pethidine in conjunction with a mixture of pot. brom. and chloral hydrate for practically all the patients admitted to hospital under my care, with excellent results. I have, like Dr. James Ross, never found that heroin had any ill effects on the infant, even though delivery followed very shortly after an injection, nor have I found any ill effects following the use of pethidine. I have not, however, given either heroin or pethidine as a routine to every patient admitted to hospital, as not every patient seemed to require it, and occasionally an injection of morphine or omnopon and scopolamine seemed preferable.

The procedure which has been adopted as a routine is as follows. As soon as labour pains have been established, but before the patient is in any way distressed, a dose of pot. brom. and chloral hydrate, of each 30 gr., is given and the patient encouraged to relax and sleep if possible. When the pains become more severe and the patient shows signs of becoming distressed either the pot. brom. and chloral is repeated or heroin 1/6 gr. or 1/12 gr. is given, according to the condition of the patient, degree of severity of pains, degree of dilatation of the cervix, and whether she is a primipara or a multipara. This may be sufficient with or without the use of Minnitt's gas-and-air apparatus at the end of the second stage, but if the first stage is prolonged more than 3 to 4 hours after the initial dose of heroin, then either heroin 1/12 gr. is given or the pot. brom. and chloral is repeated. As a rule with this medication the patient sleeps through most of the labour, and on being questioned next day has very little recollection of what she has been through. For the past few months pethidine has been used in place of heroin: 2 c.cm. (100 mg.) pethidine has been given intramuscularly in place of heroin 1/6 gr., and 1 c.cm. (50 mg.) pethidine in place of heroin 1/12 gr. The patients do not sleep after pethidine as they do after heroin, but they are, as a rule, drowsy after the pot. brom. and

chloral and remain relaxed and quiet. We have, however, continued to use heroin at night to ensure sleep and for nervous and apprehensive patients.

It is difficult, I think, to state exactly a routine method of medication to be given in every case, because individuals vary greatly, both with regard to their appreciation of pain and the rapidity or otherwise of the progress of labour, but the procedure outlined above does give very good results. In my opinion the value of these drugs lies mainly in their sedative and analgesic action rather than in any other property they may possess. To anyone who has spent much time in the labour wards it is obvious that mental and physical exhaustion of the patient prolongs the first stage of labour, and I am sure that if drugs were used in labour more freely and more adequately the bogy of the "rigid cervix" would disappear almost entirely, and many more trial labours would end successfully; also that the incidence of instrumental deliveries would be reduced. I cannot, however, agree with Dr. James Ross that heroin should be used by midwives in domiciliary practice, at the present time at any rate, but I would urge the greater use of a mixture of pot. brom. and chloral hydrate, which, even by itself, is most useful and effective.—I am, etc.,

MARGARET VENTERS,  
Obstetric Consultant, Barrow-in-Furness.

### Infant Mortality in Scotland

SIR.—Your correspondent S. F. Markham, M.P., draws attention to the fact, shown by Table VIII of the Beveridge report, that the average Scottish household of 3 to 5 persons spends 13% less on coal, gas, or electricity than the same household in Southern England. From this he deduces the entirely fallacious conclusion that less coal, etc., is actually consumed in Scotland, and that it is considered heroic and spartan to be cold. A glance at the table referred to will show that the amount spent on coal depends on the price, and the price on the distance from the coalfields. The main portion of the population of Scotland is gathered round the mining areas—Lanarkshire, the Lothians, and Fife—where, compared with the South of England, transport costs to the consumer are low indeed. The same holds good of the mining areas in England and Wales.

As shown by the table the amount spent by the average household in the north and north-east of England, and in Wales, is less than in Scotland, as would be natural in the more homogeneous and restricted areas. It would be strange indeed if households in the mining areas consumed the least coal.—I am, etc.,

Lancaster

R. T. RANKIN.

### Prevention of Goitre

SIR.—My attention has been drawn to a recently published memorandum of the Goitre Subcommittee of the Medical Research Council entitled, "Endemic Goitre in England: Argument for Preventive Action." This memorandum draws attention to the great prevalence of goitre in England and strongly urges the adoption of a national policy of adding a trace of iodine to all common salt consumed in the country.

Of course I am gratified to learn that our expert advisers have at long last recognized facts which I have been continuously stressing for the past fourteen years. In 1933 I published an article on the "Prevention of Disease," concluding it with these words: "The leading nation, from the point of view of health, will be that which realizes the value of salt iodization and puts it into general practice." More recently, however, I have recognized the fact that the wholesale introduction of iodine-containing salt in the diet of the whole community is a somewhat crude method of correcting the evident deficiency. I have practised a simpler, surer, more accurate method of accomplishing this object which is free from certain drawbacks and rests on an entirely voluntary basis.

The primary cause of goitre is iodine deficiency, and since this element is essential to normal thyroid function and, furthermore, to that of the endocrine system in general, it follows that its persistent deficiency is liable to pave the way to the various manifestations of disease in general; moreover, it becomes evident that most of our people are functioning at a lower level of real health than that of which they are

inherently capable, and that from conception onwards. We know that simple goitre *per se* is but rarely associated with serious symptoms, but, nevertheless, it is indicative of an underlying constitutional disorder affecting the harmonious working of the endocrine system, and so goitre may be looked upon as a "key disease" and iodine as the "key element."

Many years ago I noted the marked and increasing prevalence of goitre in our midst, and observed the great value of minute doses of iodine in the prevention and treatment of acute and chronic infections and of constitutional disease in general and its beneficial effects upon the general health—its value as a "food" rather than as a drug. During the past fourteen years I have published numerous articles on iodine deficiency and its deleterious effects upon the health of our people. On several occasions stress has been laid upon the great eugenic value of an iodine supplement to expectant mothers to protect them from miscarriage and puerperal complications and to ensure that the offspring be not handicapped in physical or mental development.

I am of opinion that iodine deficiency is the primary cause of goitre and thyrotoxicosis—of defective natural resistance to acute and chronic infections, and of constitutional disease in general in its various manifestations, including those two great killing diseases—cardiovascular degenerations and cancer. Apart from malnutrition due to insufficient nourishment or to a very restricted dietary—the cause of such diseases as rickets, scurvy, etc.—one may state that an ordinary rational diet has but one fault—namely, its evident iodine deficiency—and if this be corrected there is no need to worry about any mineral or vitamin supplement.

In the near future one may hope that medical attention will concentrate on the prevention of disease rather than merely on its treatment—on health rather than on disease.

Penarth, Glam.

W. MITCHELL STEVENS, M.D., F.R.C.P.

### Periarteritis Nodosa

SIR.—Dr. MacKeith, in his report (Jan. 29) upon three cases of periarteritis nodosa, leaves one with the impression—indeed the subtitle of the article implies—that the condition described is a distinct clinical entity. Would it not be more correct to say that its presence should always be regarded as a manifestation of an underlying hyper-ergy? Its association with rheumatism seems now to be well established. Neale and Whitfield (1934) discuss the clinical manifestations of periarteritis nodosa and conclude that it may be a variant of acute rheumatism; while Middleton and McCarter (1935) review the literature in some detail and consider the suggestion that it should be placed in the rheumatic group to be warranted.

My interest in the condition has been aroused by the observations of Rich (1942), and Rich and Gregory (1943) upon which you commented in your issue of May 15, 1943. Rich originally reported the study of material from several fatal cases which had received before death (a) serum alone, (b) serum + sulphonamides, or (c) sulphonamides alone. In all the histological picture was that of a periarteritis nodosa; and he suggested that the latter might well be the essential pathological lesion in those who had become sensitized to such materials. Later, in collaboration with Gregory he was able to reproduce the lesions in experimental animals. Clinically, there can now be little doubt that some of the "side-effects" of the sulphonamide series are of a "sensitization" type; and the ability to reproduce the rash and fever with a single dose of the offending drug in an individual who has shown these reactions is well known. I therefore interested me to find that in MacKeith's third case a biopsy performed on admission showed no lesion, but a repeat examination one month later after a course of sulphathiazole showed the typical histological picture. Further, all of his patients had a past history of chronic cough; it would have been valuable to have elicited precise information that this had never been treated with a sulphonamide. It would be a pity if such occasional findings were to be interpreted as raising yet another "bogy" to frighten the clinician against effective chemotherapy; and that is not the purpose of my letter. It is surely necessary to emphasize that periarteritis nodosa may occur as a result of a variety of exciting causes; that the reaction, it would seem, can frequently be related to a state of hyper-ergy on the part

of the patient; and that chemicals of the sulphonamide series may be incriminated.

One final consideration is worth recording in this connexion. It has been found that the sulphonamides are not only ineffective but may indeed be harmful when administered to cases of acute rheumatism. Can such an observed clinical result not perhaps be correlated with, on the one hand, the association of rheumatic disease and periarteritis nodosa, and, on the other, that of periarteritis nodosa and drug-sensitization?—I am, etc.,

THOMAS ANDERSON,

Annicland, Glasgow.

Physician-superintendent, Knightswood Hospital.

### Exomphalos

SIR.—My friend Mr. D. B. E. Foster (Feb. 12, p. 230) emphasizes the value of early operation, and is to be congratulated on the successful result in two of his three cases of partial exomphalos. He apparently regards operation for complete exomphalos, however, as futile, and is supported in his opinion by the references he quotes and a statement in a recent edition of a well-known textbook that "exomphalos is merely of pathological interest." That this is not invariably the case, however, is shown by the one and only example on which I have operated. The condition was complete and the liver outside the abdomen. Operation was performed without anaesthetic when the baby was only twenty minutes old. The child survived, and when last heard of was 6 years old and healthy. This case was reported in the *British Journal of Surgery*, 1941, 29, 37, and I draw attention to it here merely to encourage surgical effort in what may at first sight appear to be a hopeless condition.

"The abyss is worth a leap, however wide,  
When life, sweet life lies on the other side."

—I am, etc.,

LAMBERT ROGERS.

### Tonsillectomy in Children

SIR.—In your issue of Feb. 19 (p. 268) Mr. Carew Shaw has written an excellent letter on this subject. My experience at a provincial hospital endorses his findings.

During the past 6 months I operated on 25 children, ages ranging from 5 to 9 years, who had had their tonsils and adenoids removed under ethyl chloride anaesthesia—the guillotine being employed for the tonsils. These cases were seen by the school doctor, who recommended removal of the tonsils and adenoids, and were admitted to the hospital under the county council. In every case which was returned to the E.N.T. department by the local practitioner, the patients were suffering from nasal catarrh and obstructed nasal breathing; in 10 of these cases there was impaired hearing, and 4 were suffering from bilateral otorrhoea. On examination, the anterior pillars of the fauces were damaged in 22 instances, and tonsillar remnants were present in 12. In all 25 adenoid tissue was found in the nasopharynx.

On Mr. Norman Patterson's suggestion I continued the investigation on the weight of adenoid tissue removed in cases which had been previously operated on—using his curette to remove the lymphoid tissue from the region of the Eustachian cushion (see *British Medical Journal*, Nov. 28, 1936). The largest mass of adenoid tissue removed weighed 6.5 g., and the average weight was approximately 3.5 g. The weighing took place immediately after operation. In the cases with impaired hearing and otorrhoea, adenoid tissue was found in the fossa of Rosenmüller. Following operation patients with impaired hearing soon recovered this function. Of the 4 cases suffering from otorrhoea, the discharge became negligible in 2 within 10 days; the other 2 were operated on for drainage of the mastoid. In every instance on examining the nasopharynx at operation the Eustachian cushions were found to be hypertrophied.

I agree with Mr. Carew Shaw that little reliance can be placed on articles which have appeared in various medical journals, "purporting to show that tonsil and adenoid removal in children is at best useless, and even may be harmful." As operations are so often incomplete, statistics are founded on quite unreliable material. If I had followed the advice of these articles I doubt whether I should have had the tonsils and

adenoids removed from my own child. The tonsils and adenoids, however, were removed in an efficient manner by dissection and complete removal of all adenoid tissue. Since operation my child has put on weight, does not snore at night or suffer with nasal catarrh; her appetite has improved; but she still catches cold—the colds when they do occur are of a trivial nature, lasting 3 to 4 days. Recurring attacks of cervical adenitis accompanied by toxæmia and difficulty in swallowing are now things of the past.

I am in complete agreement with Mr. Carew Shaw when he says that "all the tonsils and nothing but the tonsils" should be removed, and that the adenoids should be removed without damage to the Eustachian tubes. I would like to stress that in my experience the "smash-and-grab" operation, which often results in incomplete removal of the tonsils, frequently accompanied by damage to the faucial pillars, coupled with very partial removal of the adenoid tissue, is much to be deprecated. —I am, etc.,

Royal Bucks Hospital, Aylesbury

S. W. G. HARGROVE.

### Doctor and Patient

SIR.—One man's editorial is another man's red rag, but humanitarians will be comforted by the thought that, in Coventry at any rate, even in wartime, it is still possible to obtain plenty of "charity" (in the shape of other people's money) and holidays-while-you-wait in return for the nimble shilling. Meanwhile let us hope that the Editor is not unduly depressed at receiving a lesson in the use and meaning of the King's English, to say nothing of a castigation for stating the truth.—I am, etc.,

Highams Park

FREDERIC SANDERS.

SIR.—In a vital industrial centre such as Coventry, the venue of Dr. K. E. Barlow's philanthropic labours (Feb. 19, p. 265), one hopes that the local doctors do not view the vexed question of absenteeism merely as a matter of science v. charity. Patriotic sentiment is wanted—an eventuality foreseen by the "Wandering Minstrel" of operatic fame, but a factor omitted from Dr. Barlow's admirable dissertation. The civilian practitioner must feel that he can do little directly to further the war effort, but it was unconscionable of him not to use his influence (if any) for the purpose of getting convalescent patients back to work as soon as possible.

Dr. Barlow's indictment of the "industrial set-up" may be unexceptional on every count; it is largely a question of political persuasion. Our cities are hideous; life in great centres of population probably fails to develop the best in man, and until recently there were over two million unemployed. But should not the inevitable attack on these "Satanic mills" be postponed until they cease to be the anvils of Vulcan which are still forging weapons for the defence of civilization?

Women will never be psychologically adjusted in large factories, but we trust their sojourn there will be short. For the most part they accept the present phase in a philosophic spirit, but too many are ready to ascribe a transient cold to the smoke and metal dust of the factory, and to seek to enlist the doctor's aid in getting out, temporarily or permanently. Even if one must eventually accede to the demands of these importunate widows, matrons, and spinsters there is no harm done by gently pointing out that the atmosphere of a battlefield can be smoky on occasion, and perhaps charged with even more harmful metallic particles. I have known it impress, but not often.

The man or woman who seems to regard six weeks as an average period of incapacity for a common cold is the more usual problem. Here again tactful exhortation on the same lines may be indicated, for sympathy with the patient must be counterbalanced by sympathy with the rest of mankind—the Forces, our Russian ally, the occupied nations, etc. Does one inadvertently pander to this tendency by labelling the smallest of colds with the grandiose title "coryza"?

Science reigns supreme in the realm of organic disease: this can usually be accurately measured and rationally treated, no two surgeons or physicians disagreeing over much. "Functional elements" form a vast hinterland, mainly uncharted and left

to the G.P., and here his manner of dealing with cases will largely reflect his personality. Dr. Barlow is rejoiced to find the G.P. so kind-hearted by nature that scientific justice is liberally tempered by charity. We may trust they are also public-spirited men and women, and that the charity is tempered in its turn by wider considerations.—I am, etc.,

Birmingham.

PETER PARRY.

### A Health Magazine for the Layman

SIR,—Dr. Joseph Parness's comments (Feb. 19, p. 270) are timely, and many doctors, and still more patients, will be in agreement with his outcry against so-called "health magazines" and his plea for a proper journal for lay reading.

There must be others besides myself who look forward to the arrival each month of *Hygeia* (the health magazine of the American Medical Association), but regret that we have to send to America for a periodical which gives our patients what they want. The American Medical Association realizes the demand for reliable instruction on health and disease, and appreciates also that there are many people who have a genuine interest in such matters, an interest which is not based on morbid curiosity. My own copies of *Hygeia* pass through many hands before they reach the waiting-room table, and thereafter are sent on to others whose chief request previously was for old copies of the *British Medical Journal*. While *Hygeia* is produced on typically American lines, its articles are contributed by properly qualified people, the style and subject-matter are appropriate, and the information given is reliable.

That there is a demand for knowledge and guidance on health and disease is shown by the avidity with which the average layman reads the pseudo-health journals and articles in the popular press. I am fully aware that there are some reasons against the publication in this country of such a journal as *Hygeia*, but a time has come when steps should be taken to satisfy the acknowledged appetite of the laity by providing a periodical, officially sponsored, attractively produced, written in popular style, and giving accurate information of topical interest. Such a magazine must help the American reader to understand his body, keep well, tolerate disease with less apprehension when it overtakes him, contribute to national health, and, by rendering the patient more enlightened, help his doctor.—I am, etc.,

Leicester.

F. S. AIREY.

\* The Central Council for Health Education publishes two journals for the layman: *Health Education Journal*, a quarterly (1s. 6d. per copy, 6s. per annum, post free), which is of special interest to those concerned with health education; and *Better Health* (2d. per copy, 3s. per annum, post free), a monthly, containing a variety of articles on health topics of interest to the general public.—ED., *B.M.J.*

### Trilene Hazard

SIR.—Dr. H. Joules invited me to the Central Middlesex Hospital to help to investigate the cause of cranial-nerve palsies which developed in some patients following general anaesthesia. These, I learn, are reported in this issue of the *Journal* by Humphrey and McClelland.

R. Milton and J. Graham, working in the laboratories of this department, have shown that dichloroacetylene is the only substance formed in any quantity when trichlorethylene is passed over soda-lime, as evidenced by the isolation of the "dibrom" derivative, which has a well-defined boiling-point—172° C. With K. M. A. Perry they have performed experiments on rats. Two control rats were placed in a chamber and were anaesthetized by sucking trilene through it for thirty minutes; they both recovered. Three others were similarly exposed to a trilene-dichloroacetylene mixture for 30 minutes, and all three died in convulsions after being removed. Further experiments and histological studies are being carried out.

These experiments support the evidence of Humphrey and McClelland that trichlorethylene reacts with soda-lime to form a toxic substance, dichloroacetylene. Trilene should therefore never be used in a closed-circuit anaesthetic apparatus.—I am, etc.,

DONALD HUNTER.

Department for Research in Industrial Medicine,  
London Hospital, E.1.

## First Aid for Thermal Burns and Scalds

SIR.—A forthcoming issue of the *British Journal of Industrial Medicine* will contain a report by Mr. T. Gibson, Prof. J. P. Todd, and myself on an investigation recently carried out at the Glasgow Royal Infirmary on behalf of the Medical Research Council. We had been impressed by the absence of any agreed policy with regard to first aid for burns, and we have attempted to find a satisfactory basis for such a policy. The experimental data can await publication within a few weeks, but, in view of the recent renewal of enemy activity against our civilian population and the likelihood of a large number of burning injuries, it seems expedient to submit the conclusions we have reached. They are, briefly, as follows:

1. In all severe or extensive burns no first aid should be attempted, other than keeping the patient warm and giving morphine, if required. Immediate removal to hospital is the first consideration.

2. Small burns which are accessible without removal of clothes—e.g., of the hand or forearm or head—should be covered with a recently laundered clean towel or, better, if it is available, with a sterile cloth. (Industrial premises or private houses in areas likely to be attacked by incendiaries should keep a supply of such cloths, previously baked in an oven and stored in a tin.) The burn thus covered should be sent without delay to the factory surgery or a hospital or a private doctor.

3. When quite superficial small burns are treated at home, or when, in the case of more severe burns, their full-dress treatment cannot be carried out without considerable delay, the burned area and the skin around should be freely smeared with a water-soluble antibacterial cream. The cream which is recommended ("Glasgow No. 9"), on the basis of extensive clinical and bacteriological trials, has the following formula:

Cetyl trimethyl ammonium bromide	.. .. .	1.0 g.
Sulphanilamide	.. .. .	3.0 g.
Castor oil	.. .. .	25.0 g.
Beeswax	.. .. .	1.8 g.
Wool fat	.. .. .	1.8 g.
Cetyl alcohol	.. .. .	5.0 g.
Glycerin	.. .. .	10.0 g.
Water	.. .. .	52.4 g.

**Preparation.**—Melt the castor oil, beeswax, and wool fat and cetyl alcohol at as low a temperature as possible. Dissolve the CTAB in the water with the aid of heat and mix with the oil, etc., at about 60° C. and stir till set. The sulphanilamide is then rubbed up with the glycerin and incorporated, with thorough mixing, in the cream. A "peerless mixer" with bent arm at slow speed has given the best results, but it is quite possible to make the preparation by hand, although not quite so well. [NOTE: This cream cannot be heated to sterilize it, but it can be regarded as self-sterilizing for the ordinary non-spore pathogens. Samples experimentally contaminated with *Staph. aureus*, *B. proteus*, and *Ps. pyocyanea* have always been found free from viable organisms after 24 hours. It is possible that spores of pathogenic clostridia, including tetanus, might survive in it (this point is being investigated), but the risk of such contamination may be regarded as extremely small. When the cream is to be kept for long periods chlorocresol (0.2%) could be added to it to prevent any growth of moulds.]

his cream should be applied with a knife-blade or spoon iously sterilized by dipping for 2 minutes in boiling water passing through a flame. The burn should not be washed before the cream is applied, nor the blisters be snipped. It should not be left on the burn for more than two days, because prolonged application involves a slight risk of inducing a sensitization dermatitis.

4. All first-aid procedures should be carried out with due precaution against the transfer of streptococcus to the burned surface. (Apart from "shock," this is by far the most serious risk for the burned patient.) Hands should be washed and dried before carrying out any treatment, and a mask or clean handkerchief should be worn over the mouth and nose.

If cream is applied the burn should afterwards be wrapped in a sterile cloth and bandage, or in a recently laundered towel. On no account should blankets be allowed to come into direct contact with the burns, because they are frequently contaminated with pathogenic organisms.—I am, etc.,

Birmingham.

LEONARD COLEBROOK.

## Obituary

JOHN FAWCETT, M.D., F.R.C.P., F.R.C.S.

Dr. John Fawcett, consulting physician to Guy's Hospital, who died in London on Feb. 18, aged 77, was the son of John Bisdee Fawcett of Lloyds and was educated at Dulwich College and at Guy's Hospital Medical School. He graduated M.B., B.S. Lond. in 1890 and took the M.D. in the following year, and soon afterwards the F.R.C.S. At Guy's Hospital he held a succession of posts, and for a time he was assistant physician to the Royal Free Hospital and Beane research scholar in materia medica. His early teaching appointments at Guy's were those of demonstrator in morbid anatomy and curator of the Museum; later he became Dean of the Medical and Dental Schools, and after retirement a Governor of the Medical School. In 1902 he was elected F.R.C.P., and he served the College as examiner for four years, councillor in 1920, censor for the three following years, and representative on the Senate of the University of London; he also examined in medicine for the universities of London, Sheffield, and Wales. During the last war he held a temporary commission in the R.A.M.C.

Dr. Fawcett joined the B.M.A. in 1893 and was vice-president of the Section of Medicine at the Annual Meeting at Nottingham in 1926. Two good causes in which he took a keen personal interest were Epsom College, on whose council he served, and the Invalid Children's Aid Association, of which he was vice-chairman. For four years he was the representative of the Board of Education on the General Nursing Council. He was also a member of the departmental committee on morphia and heroin addiction, and of the Ministry of Pensions disability committee.

We are indebted to Sir WILLIAM HALE-WHITE for the following appreciation:

John Fawcett had many sterling qualities: perhaps the most conspicuous was his efficiency. Whatever he undertook he did well. This was shown in his student days both at football and in his examinations, for not only did he take his Fellowship of the College of Surgeons but also his M.R.C.P., later becoming F.R.C.P. He had a very strong sense that, at whatever inconvenience to himself, he must carry out to the best of his ability that which he had undertaken. This outstanding sense of duty led to his nickname among the students of "honest John," an affectionate title well deserved. They looked up to him as an example of what a physician should be.

It is easy to understand that such a man was of the greatest value to a teaching hospital; he was always punctual in his visits, and his house-physician could depend upon his advice at any hour. He rightly considered that he was not only to look after the patients but also the students, and he took great pains to teach them. He had considerable ability as a teacher, and many generations of students owe much to him. It was a pleasure to him also to help them in their recreations by presiding over many of their clubs, such as the football. He was likewise always willing to serve conscientiously on the many committees connected with the hospital and school. For a time he was dean. Guy's Hospital and Medical School could not possibly have had a more devoted servant than John Fawcett, who always considered both of them to come before everything else. They, too, owe him much. Everyone felt that he took so much trouble, not in the slightest degree to benefit himself: it was said of him that he was one of the few who never had an enemy.

After he retired from active work at Guy's his old school Dulwich, the Invalid Children's Association, and Epsom College were fortunate enough to secure his help. He laboured for them all with his characteristic unselfishness and devotedness, and they all benefited. To Epsom he was treasurer: this meant much hard work not only at the London office but at Epsom. He took regular holidays, mostly in Scotland; whenever he could he got a day's shooting or golf or a good walk, but during the later years of his life he suffered miserable health. Many would have given in: not so John Fawcett: he strove hard at his voluntary tasks whenever it was physically possible. Like Johnson, he said, "I will be conquered, I will not capitulate."

## W. R. CAMMOCK, M.B.Glas., F.R.C.S.Ed.

Mr. W. R. Cammock, who was widely known as an aural surgeon in the Oldham and Rochdale districts of Lancashire, collapsed while driving his car on Feb. 4 and died shortly afterwards in hospital. His death in the prime of life has come as a great shock to his friends and has robbed South-East Lancashire of a very able surgeon.

Born in 1886, he was the only son of a Glasgow solicitor, and in that city he was educated, first at Hutchison's College and later at the University, graduating M.B., Ch.B. in 1906. After holding house appointments in Glasgow, where he was house-surgeon to Sir William Maclewen, he went to Stockton-on-Tees Hospital as resident surgical officer, and in 1911 took the F.R.C.S.Ed. Then followed a brief period in general practice, but, deciding to make aural surgery his career, he became resident aural surgeon at the General Infirmary at Leeds. He continued his studies for some months in Vienna, and in 1914 settled in Oldham, where he was soon appointed to the staff of the Royal Infirmary. There he rapidly developed a large and efficient ear, nose, and throat department and gained a wide reputation as an able clinician and operator. He was also on the staff of Boundary Park Hospital, Oldham, and, in more recent years, was appointed aural surgeon to Rochdale Infirmary and Birch Hill Hospital. In developing his specialty in this district of Lancashire Cammock worked single-handed and was something of a pioneer. He worked with great zest and read widely, keeping himself abreast of all modern developments. There was nothing stereotyped and rigid about him, and he was always willing to abandon old methods to achieve improvements. In recent years he had adopted the intrameatal approach to the mastoid with excellent results. He held, too, that it was the surgeon's job to adapt himself to human needs. It was this view which led him to take up thyroid surgery and to regard it as coming within the province of the laryngologist. When he settled in Oldham the incidence of goitres was very high indeed, and he addressed himself to the problem with characteristic zeal, becoming a real expert in the surgery of the thyroid. In all his work he set a most high professional standard.

Mr. Henry Poston, a colleague for many years, writes: He died as he would have wished, working at full pressure and at the height of his power. It seems hard for us who have long known and appreciated the man and his work to realize that no more will we hear him discuss and discourse on current surgical literature. For Cammock's reading and knowledge were catholic, and he was invariably *au fait* with the major advances in surgery. Essentially a clinician, he possessed an infinite capacity for taking pains and for attending to the detail of his work. In his heavy clinics he would listen as carefully and sympathetically to the last patient as he did to the first. He was a careful and courageous operator, keeping his eye on the patient and ignoring the clock. For many years he struggled obstinately against the bridle of Theages—chronic ill-health. He might perhaps have taken things more easily, but the line of least resistance was not his choice, and he gave the unforgiving minute its full sixty seconds' worth of distance run. To the Oldham Royal Infirmary he devoted the greater part of his long and strenuous professional life, and actually, at one period, supervised the x-ray and physiotherapeutic departments of that institution in his own serious and scrupulous way. Cammock had the inestimable gifts of being able to teach and inspire his house-surgeons, and not a few of those whose Gamaliel he was now occupy positions of influence and eminence in the realm of aural surgery. He was gentle but firm, knew what he wanted and saw that he got it. He never did any ill, and the good he did cannot be interred with his ashes.

## FRANK HINDS, M.D.

Dr. Frank Hinds, consulting surgeon to the Worthing Hospital, died in retirement on Feb. 5, aged 82. He had been president of the Brighton and Sussex Medico-Chirurgical Society in 1910, president of the Sussex Branch of the B.M.A. in 1922, and chairman of the Chichester and Worthing Division in 1927-8.

Mr. Herbert H. Brown writes: Frank Hinds entered University College Hospital as a student in 1880. At that time strict Listerian methods were practised by two of the younger surgeons, Marcus Beck and Rickman Godlee, and accepted by most of the younger men, including the resident staff. Victor Horsley was Frank Hinds's most intimate friend from childhood, a friendship which continued without interruption until Horsley's death in Mesopotamia in 1916. Hinds held the posts of H.P. and H.S. at the hospital and deputized for the R.M.O. He was a good diagnostician and surgeon, but his most outstanding quality was his unfailing courtesy and consideration for others: he was by far the most universally popular man of his time. He left in 1887 after taking his M.D.Lond., and became R.M.O. at the Hospital for Sick Children in Great Ormond Street, and then spent two or three years travelling about the world. On

his final return to England he accepted a pressing invitation from a U.C.H. friend, Dr. W. A. Gosling, to join him and his partner at Worthing. He was at once asked to serve on the staff of the hospital, at that time a small institution of only 27 beds. His great diagnostic ability and surgical skill and resourcefulness in any emergency brought him patients from all parts of Sussex, and during the course of his career at Worthing he performed with complete success several strikingly original and formidable operations. Perhaps the most remarkable was the complete and successful eradication of a large myeloid sarcoma of the femur at the Worthing Hospital in 1895. The case was recorded in the *B.M.J.* in April, 1908; it aroused great interest among American surgeons, and inquiries were made about the patient. Following an attack of encephalitis lethargica in 1920 Dr. Hinds's health, which had hitherto been good, began to fail seriously. From this disease and its sequelae he never completely recovered, and in 1922 he resigned from the hospital and from active surgical work, though continuing to see some of his patients until 1928, when he finally retired. He never lost the affection of any of his patients, nor of his medical colleagues and other friends.

A former colleague writes: No name in Worthing stood higher in public esteem than that of Frank Hinds in the prime of his career. He held a record at the Worthing Hospital remarkable alike for quality and length of service. It was a well-deserved tribute to his work that when in 1927 No. 1 Ward, the male surgical ward, was opened as part of a major reconstruction it was named after him. In his life-work we have seen general practitioner surgery brought to its highest development and highest scope of usefulness. Courtesy and kindness marked his dealings with professional colleagues; to him they turned as a friend and wise counsellor. He was ever ready to give encouragement to his juniors and to help with his opinion on a difficult case.

## THE LATE DR. G. C. ANDERSON

Sir Stanley Woodward, Master of the Society of Apothecaries of London, has sent the following letter to Viscount Dawson of Penn as President of the British Medical Association: "I had the unhappy duty of informing the Court at their recent meeting of the death of Dr. George C. Anderson, and I was asked to convey to you as President of the British Medical Association an expression of the Court's most sincere sympathy in the irreparable loss which the Association has suffered by the passing of its able Secretary. Not only the Association but the nation has suffered a great loss, and his innumerable friends, both in and out of the profession, a personal bereavement. His foresight enabled him in peacetime to prepare for the situation which would inevitably arise in the event of war, and his untiring efforts to ensure that the transition from war to peace should be accomplished as smoothly as possible will long be remembered. I shall be grateful if you will convey to your Council this Society's deep regret."

Dr. T. C. Routley, General Secretary of the Canadian Medical Association, has sent the following letter to Dr. Charles Hill: "We were deeply grieved to learn from your wire that Dr. Anderson had passed on, and we immediately sent you the following message: 'Very sorry to learn of Dr. Anderson's death. On behalf of Canadian Medical Association may I express sincere sympathy to the bereaved family and the British Medical Association.' Dr. Anderson was a grand fellow and one whom a great many of his colleagues on this side of the water were proud to claim as a friend. No doubt pressure of work and anxiety in recent months hastened his end, adding one more to the appalling toll of this terrible conflict. He will long be remembered with admiration and respect. On behalf of the Canadian Medical Association may I convey to officers and members of the British Medical Association sincere sympathy."

## The Services

Sir Morton Smart has been appointed civil consultant in physical medicine to the R.A.F.

The *London Gazette* has announced the appointment as M.B.E. (Military Division) of Surg. Lieut. R. M. Macintosh, R.A.N.R., for courage, endurance, and devotion to duty; and Temp. Surg. Lieut. C. F. Cooper, R.N.V.R., has been mentioned in dispatches for services to the wounded after an enemy air attack.

The *London Gazette* has announced the award of the M.C. to Capt. H. M. Jones, R.A.M.C., in recognition of gallant and distinguished services in Italy.

## Universities and Colleges

### UNIVERSITY OF OXFORD

An election of two members of the Board of the Faculty of Medicine will be held on May 31. The members elected will come into office on the first day of Michaelmas Term, 1944, and will hold office, the senior for two years and the junior for one year from that day. The General Medical Electorate consists of all Oxford graduates in medicine who are members of Convocation. The Board of the Faculty of Medicine includes two members elected by the General Medical Electorate who must be members of that body and of whom one at least must be a person engaged in teaching one or more of the clinical subjects of the Faculty. Nominations of duly qualified candidates for election will be received by the Secretary of Faculties at the University Registry up to 10 a.m. on Wednesday, May 10. Each nomination must be signed by six members of the General Medical Electorate, and no candidate will be eligible whose nomination has not been received by that date.

### UNIVERSITY OF CAMBRIDGE

The following have been examined and approved for the degree of M.Chir.: B. N. Brooke, A. G. McPherson.

### UNIVERSITY OF LONDON

At a meeting of the Senate held on Feb. 23 the title of Professor Emeritus of Bacteriology in the University was conferred on Sir John C. G. Ledingham, F.R.C.P., F.R.S., on his retirement from the professorship of bacteriology at the Lister Institute of Preventive Medicine.

The degree of D.Sc. has been conferred on A. G. McDonnell Weddell, M.D., an internal student at St. Bartholomew's Hospital Medical College.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND

Prof. A. J. E. Cave will give a series of Arnott demonstrations and museum lecture-demonstrations, open to advanced students and medical practitioners, at the College (Lincoln's Inn Fields, W.C.) on Mondays, Wednesdays, and Fridays, from March 6 to 24, at 4 p.m.

## Medical Notes in Parliament

### Report on Infant Mortality in Scotland

Major MARKHAM drew attention on Feb. 16 to infant mortality in Scotland. He recalled that up to 1941 this mortality rose rapidly, and that on July 8, 1942, the Secretary of State for Scotland had said the figure per 1,000 births rose from 68 in 1939 to 83 in 1941. The Minister then announced that he had asked the Scientific Advisory Committee of the Department of Health for Scotland, under the chairmanship of Sir John Boyd Orr, to consider and report quickly on the causes of this rise and to suggest remedial measures. Major Markham asked who had changed those terms of reference. Changes in diet, housing, employment, and medical services had a profound effect on infant mortality during the war years, and if the committee had carried out its original terms of reference its findings would have assisted not only Scotland but the Empire generally. He understood that Sir John Orr denied that he had anything to do with the subcommittee which drew up the report. Major Markham contended that much information relating to the war years was available. He complained that the report made no detailed comparison with Iceland, which was comparable to Northern Scotland, nor to great American cities that might be compared with Glasgow, nor to Australia. He objected to the declaration in the Minister's introduction to the report that remedies for infant mortality must be found in the immediate post-war years. The obvious question was, Why not now?

The statistical basis of the report, he continued, was poor. It did not mention that changes were due to war conditions, such as reduction in employment and poverty and change in diet. There was no reference to the fact that calcium and vitamin B<sub>12</sub> had been added to national bread. There was no reference to problems caused by evacuation nor to the effect of fuel shortage on infant mortality. There was no mention of vitamin E, the reproduction vitamin. There was no information on the difference between infant death rates in ordinary homes and in institutions. Most of the overseas comparisons were from 6 to 10 years old. There was no mention of the new Simpson Memorial Hospital in Edinburgh, which had air-conditioned

wards; whether these were successful or not. The report should have paid attention to environmental condition including smoke and fog and temperature.

Mr. JOHNSTON, in replying, said that although Major Markham had raised the subject on the adjournment the Government's promise to afford facilities for an adequate discussion on it still held good. The Boyd Orr Committee did not analyse the wartime trend because there was little published information for the war years. They said that the most important environmental conditions of diet, housing, employment, and medical services were highly abnormal in most areas. That was true. They said it was impossible to judge to what extent changes since 1939 were likely to be permanent. Mr. Johnston thought it would have been desirable to analyse wartime trend because Scotland last year had the lowest infant mortality in its history—65 per 1,000. Five members of the committee had knowledge of the conditions abroad. Dr. Douglas, chief maternity and welfare officer of the Department of Health, had knowledge of New Zealand; other members had been to Scandinavia and knew conditions there. As for fuel, the Scottish consumer saved about 13% less coal than the English householder, but Titmuss had shown that fuel conditions were not the cause of the infant mortality in Holland, and had drawn attention to the fact that in Iceland the rate was 28.3 per 1,000 live births. Titmuss therefore judged that the heating of the household was not a primary factor. It was true that the New Zealand figure was 29, but that excluded the Maori, which was 97. In July 1939, the unemployment figure in Scotland was 11.5; in January 1944, it was down to 1. Mr. Johnston believed that a factor causing a reduction in the infant mortality was that more purchasing power was coming into the home. Maternity homes had gone up by 50% during the war, although 108 maternity beds in rural areas were being put to wartime uses. Local authority associations promised to do all they could by increasing the intake of orange juice and vitamin tablets and by requisitioning more large houses.

### Shelling of Field Medical Units

On Feb. 22 Mr. SORESENSEN asked the Secretary of State for War if he would make a statement respecting the bombing and shelling of field hospitals respectively on Feb. 7 and 10 in the Anzio area; and whether, generally, the immunity of the Red Cross was being observed. Sir J. GRIGG: I could not give a categorical answer to this question without considerable investigation. There have been certain incidents, but, generally speaking, so far as field medical units are concerned the immunity of the Red Cross emblem has been respected. No official report has reached me that it has in fact been violated in the Anzio area.

### Penicillin

Mr. ATTLEE told Sir William Davison on Feb. 24 that he knew Prof. Fleming had made no financial profit from his discovery of penicillin. Others had played an important part in showing the full value of Prof. Fleming's original observation and in developing it as a discovery capable of practical application. The question of financial rewards for medical discoveries had been carefully examined on earlier occasions, with the conclusion that any such system, even if desirable, could not be administered equitably in practice. The policy of the Government was to support medical research work in progress and not to offer payments on the basis of results.

In reply to Commander Locker-Lampson on the same date Mr. CHARLES PEAT said penicillin was not a proprietary article. It was at present being manufactured only under Government auspices. Manufacture would be controlled so long as that was necessary in the national interest.

Mr. LAW announced on Feb. 23 that, owing to the interest taken in penicillin, several hundred copies of the current number of the *British Medical Bulletin* had been printed for distribution to members of the medical profession in the United Kingdom. This *Bulletin* was produced by the British Council to keep medical circles abroad informed of medical research work in the United Kingdom. Owing to paper shortage only a few copies of each number were available in this country.

*Cholera and Smallpox in India.*—Mr. BUTLER, replying for Mr. Amery on Feb. 17, stated that in India the cholera and malaria situations were improved, but incidence was still abnormally high. Smallpox also presented a problem. He had no complete figures for cases treated, but up to Jan. 29 over 2,000,000 cholera inoculations and 1,500,000 vaccinations had been performed. Mr. Amery was endeavouring to obtain exact figures of deaths in India from starvation and resulting diseases.

*Disability Claims for Pneumococcosis.*—Mr. HERBERT MORRISON told Mr. Henry White on Feb. 9 that since July 1, 1943, when the Pneumococcosis Compensation and Benefit Schemes came into operation, the Medical Board granted certificates of disablement or suspension in two cases under the compensation schemes in the North Midland Region and refused 25. One death was certified

## TWO WHOOPING-COUGH VACCINES: *Standard and Forte*

○ Whooping-Cough Dissolved Vaccine overcomes the earlier difficulties associated with vaccine therapy such as toxicity, and delayed antibody response.

This dissolved vaccine is prepared from strains in phase 1. The bacteria are in solution. The antigenic content of the vaccine, being in solution, is immediately available for uniform antibody production. The solvent, sodium lauryl sulphate, is not only non-toxic, but also reduces the toxicity of the vaccine.

Each cc. contains the antigens of *H. pertussis* 10,000 million.

Many doctors prefer to give whooping-cough vaccine in large doses. To meet this need we introduced in 1933 an additional whooping-cough vaccine of high potency to provide large doses in the usual small bulk.

Each cc. of Whooping-Cough *forte* Dissolved Vaccine contains the antigens of 50,000 million *H. pertussis*.

### DISSOLVED VACCINES

*Standard* 5 and 25 cc. bottles. *Forte* 5 cc. bottles.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX. BYRON 3434

## Economy in Disinfectants

### USE OF HYPOCHLORITES RECOMMENDED

In a statement on economy in the use of certain types of disinfectants in short supply the Therapeutic Requirements Committee of the Medical Research Council emphasised the necessity of selecting "those materials which are most readily available." Among the substances recommended to replace those in short supply for special purposes are "hypochlorites."

*Milton*, the Hypochlorite Antiseptic, has been recommended in recent medical and pharmaceutical literature or in statements by authoritative bodies for many uses including the following:—

#### *As an antiseptic and therapeutic agent*

In the Envelope Irrigation treatment of wounds, burns and ulcers.

Treatment of simple boils, carbuncles, whitlows and any septic wounds.

Treatment of mustard gas burns.

#### *As a general sterilising agent*

For the sterilisation of the new standard Jaconet, Battiste and Artificial Silk Waterproof Dressings.

For the sterilisation of non-metallic sick-room utensils and instruments.

For the emergency sterilisation of water.

For the disinfection of air in operating theatres, hospital wards, air-raid shelters, offices, etc.

Details of references and information with regard to these and other uses of *Milton* may be obtained from the Medical Dept., *Milton Antiseptic Ltd.*, John Milton House, London, N.7.

## MILTON THE STANDARD HYPOCHLORITE

*Milton* is the stable brand of electrolytic sodium hypochlorite, standard strength (1%) and low alkalinity

## INCOME TAX

## Cost of Laying up Car

R. M. since joining the Army has incurred sundry expenses in connexion with the car he formerly used in civil work. Can he claim an allowance for such expenses?

\* No; they are not incurred in the performance of the duties for which he is now being remunerated.

## "Pay as you Earn"

W. S. asks as to the effect in his case of Clause 8 of the new Bill.

\* The effect is that if his increase of salary is not in the ordinary course of events, he can be charged tax on the amount of the increase and, as regards that tax, will have to pay it in full—i.e., without the benefit of the 7/12ths "discharge" (or forgiveness) which will apply for 1943-4 to the normal ease and to the original assessment.

J. M. is employed in the E.M.S. at a salary of £650 a year and asks how he stands as regards "pay as you earn."

\* Presumably tax is being deducted from his salary under the provisions applicable to persons in the employment of the Government, and not under the general deduction scheme applicable to persons in private employment. If that is so he is not affected by the "pay-as-you-earn" scheme.

## Service in India

W. C. is serving in the Indian Army Medical Corps and is entitled to a reduced share in the profits of a British practice. What is his position generally?

\* In the first place he is not liable in respect of his Indian Service pay. In the second he cannot claim the full amount of the personal allowances, but only the proportion which his British—i.e., liable—income bears to his total income (whether liable or not). Thus if his only other income is, say, £1,000 from Indian pay, he will be entitled to 500/1,500 of the allowance for children, the personal allowance of £140, and so on. Further advice cannot be given without details; W. C. is recommended to get into touch with the Inspector of Taxes for the area in which the practice is situated.

## Flat Provided—Schedule A Tax

"LAMBDA" is employed as an assistant; his principal provides him with a furnished flat, rent and rates free. Who should pay income tax on the annual value of the flat?

\* The tax on the value (as unfurnished) is assessed under Schedule A on the statutory "occupier." In the case of a furnished flat the person to whom the furniture belongs is regarded as the "occupier" and is no doubt the person named in the assessment. He, and not "Lambda," is legally responsible for payment of the Schedule A tax.

## LETTERS, NOTES, ETC.

## The Record in Urinary Calculi

Mr. T. L. CHAPMAN, F.R.C.S., writes from Glasgow: Your correspondents on this subject may be interested in a note which I published (*Brit. J. Urol.*, 1942, No. 3, p. 131). This concerned a case where an enormous number of well-formed, almost spherical, calculi were removed from the bladder and diverticula of the bladder: 750 of them were arranged and photographed for me by a colleague and the photograph was published. In such cases it is difficult to say what constitutes a calculus, and there is not much to be gained by discussing the record number. We may find ourselves "numbering sands" like the "poor duke" in "Richard II."

## Professional Confidence

Dr. D. SAKLATVALA (West Bromwich) writes: The correspondence in the *Journal* of Feb. 12 on the Mosley affair has brought to my mind a problem which has long puzzled me. Ever since I embarked on medical practice ten years ago I have wondered why I must put clinical details on panel certificates, work certificates, school certificates, and similar documents. I have always felt that a simple statement that the patient is unfit for work, school, or what not, should, if given in writing by a medical man, suffice. At some time in the dim past the profession has failed to insist on this—it rightly could have insisted—and the present widespread demands for clinical details of our patients, as cited by Dr. Noordin, are no more than the natural result of our past laxity. Can we not even now, and at the risk of much opposition, put our house in order in this respect?

Dr. C. W. F. MCKEAN (London, W.6) writes: I was disappointed to see that only one correspondent replying to Sir Farquhar Buzzard's letter took up the vitally important point of patients' loss of professional secrecy and confidential treatment through the present-day universal demands for medical certificates giving the nature of the incapacity. Although full information should be given

to medical boards, the majority of certificates are for lay person who should have no concern with the complaint. They may know the patient socially or live in the same district. In any case a little knowledge is a dangerous thing. As a worker in venereal diseases I am particularly interested in this question of privacy, but apart from this, I would ask the profession to consider this point and to demand that patients should be given secrecy for all complaints as a matter of course. A step in the right direction was made with milk certification, but after that success the matter hung fire.

## Marginal Gingivitis in School-children

Dr. A. E. W. MILES, L.D.S. (London, W.1) writes: In the reply under this heading (Feb. 5, p. 207), attention is correctly drawn to the fact that mouth-breathing is the commonest cause of anterior marginal gingivitis in children. But no details are given of the methods to be adopted to correct this habit, which is harmful to the health of the gingivae and inimical to the growth of the jaws, and removes the intermittent positive intra-oral pressure of nasal respiration, to mention only the dental aspects of mouth-breathing. Nasal patency being present, nasal breathing is re-established in the daytime by lip exercises, which consist of holding a small flat object, such as a button, lightly between the lips for at least one hour a day, the more frequently the better; at night, by the wearing of an oral shield, which is easily made by a dental surgeon.

## Halitosis

Dr. A. D. McDWYER (Dublin) writes: In the answer to the query on halitosis (Jan. 29, p. 172) no reference was made to the excellent annotation in the *Journal* (1942, 1, 530) on the experimental work of Crohn and Drosd. Briefly, odorous substances are mainly absorbed in the small intestine and stored in the liver, from which they go into general circulation for 48 hours. In unexplained halitosis a low-fat diet (40 to 60 g.) gives relief. It is thought that certain offensive volatile products of fat digestion pass to the liver and from there are slowly given off in general circulation. May I also add that either dental sticks or floss provide the best method of removing food particles retained between the teeth where both a toothbrush and mouth washes fail. An early atrophic pharyngitis is a common unrecognized cause and can be reduced to a minimum and prevented by a well-ventilated bedroom during sleep.

Dr. W. STUART THOMSON (Edinburgh) writes: Referring to the answer to a question on halitosis in your issue of Jan. 29 (p. 172) I venture to suggest that the connexion between halitosis and the alimentary canal distal to the pharynx is not sufficiently stressed. Surely we are all aware of cases of a temporary halitosis accompanying (? due to) a temporary digestive disturbance. Why should not chronic indigestion, constipation, colitis, etc., be accompanied by fetor oris in a similar manner? Might I also suggest that once a sensitive type of person is aware of having a fetor oris it tends to be accentuated or perpetuated by the mental factor.

## An Old Midwives' Tale

Dr. W. RADCLIFFE (Wivenhoe) writes: Referring to the note entitled "An Old Midwives' Tale" in the *Journal* of Feb. 19 (p. 271), the idea that an 8-months foetus is less viable than one of 7 months goes back at least 200 years. In Spencer's *History of British Midwifery* John Maubray is quoted as stating in 1724 that a 7-months foetus is favoured in astrology because of the magic number 7; but the eighth month is peculiar to the planet Saturn, and a child born under this planet is always weak and, if it survives, has a tender constitution, if it is not indeed half-witted also. Perhaps the modern astrologers have something to say about this.

## Retarded Speech

Dr. DOROTHY RICHARDSON (Cornwall) writes: With reference to your answer to the question on retarded speech appearing in the *Journal* of Jan. 29 (p. 171), I should like to mention that my eldest boy, with normal hearing and perfectly intelligent, didn't speak a word until the age of 3½, when within a week he tackled dozens of words, many quite long ones such as "periwinkle," "elephant," etc. I am told my husband's cousin, who is a successful chartered accountant, never said a word until he was 4, so possibly there is some familial trait. I have also heard of similar cases in other families. I am writing this so that the questioner may, if he is satisfied that the child is not deaf or mentally deficient, reassure the parents that there is still hope until the age of 4. In the cases mentioned above no treatment was given and the children were brought up as ordinary children are.

## Tuberculosis Associations

We are asked to state that the National Association for the Prevention of Tuberculosis, the Tuberculosis Association, and the Spero Fund for the Industrial Welfare of Tuberculous Persons have no connexion whatever with an organization called the "T.B. Association," whose registered office is at 195, Fore Street, Angel Place, Upper Edmonton, N.18.

## TOXIC EFFECTS IN WOMEN EXPOSED TO INDUSTRIAL RUBBER SOLUTIONS

BY

J. L. HAMILTON-PATERSON, M.D.  
*Pathologist at Redhill County Hospital, Edgware*

AND

ETHEL BROWNING, M.D.  
*H.M. Medical Inspector of Factories*

This paper is the result of two years' investigation of the effects of industrial rubber solutions on the workers using them. Nowadays these are almost exclusively women. The solutions contain varying amounts of benzene and of the aromatic hydrocarbons benzene, xylene, and toluene; xylene and toluene are less toxic than benzene, but the latter is still used because of the difficulty of obtaining the former in sufficient amounts. Factory conditions have been much improved in recent years, and fatal cases of benzene poisoning are fortunately extremely rare; but even mild benzene intoxication may lead to irreversible changes in the haemopoietic bone marrow; also some people seem particularly susceptible, and develop signs of poisoning with only a limited exposure, particularly pregnant women (Meda, 1922; Hamilton, 1925; Smith, 1928; Hamilton-Paterson, 1941). It was hoped that as the result of this investigation it would be possible to identify early cases of benzene absorption and remove them from contact before any permanent changes ensued. That this is possible will be clearly shown, and also that, with suitable periods of "rest," no harm will accrue to those who continue to work under these conditions.

Rubber solutions are used for a variety of purposes in industry, but this investigation was confined to their employment in a special manufacturing process in the aircraft industry. The examinations were carried out in 13 factories scattered over the country. The investigation has been conducted in two parts. In the first, sample groups in each factory, totalling 200 women, were clinically examined and had blood counts made. These counts have been compared with the counts of 200 control women. In the second part of the investigation all the women working in one factory have been similarly compared with a group of women in the same factory who had never been in contact with rubber solution. The effects of "rest" were also studied in this group of women. The manufacturing process in question involves the use of rubber solution and adhesive "cements" which contain aromatic hydrocarbons varying in strength from 5 to 20% in practically all some proportion of this is benzene. Even though adequate ventilation is provided, as required under the India-rubber Regulations, 1922 (S.R. & O. No. 329), it is almost impossible for a woman working in certain positions with a brush and an open pot of solution, not to inhale the fumes. In this way she is probably exposed to a concentration of benzene nearly as high as that in the solution itself. The practice in some workshops, under intensive production, of allowing large numbers of treated articles to remain in the workroom until perfectly dry may result in a further increase of the general atmospheric content of benzene. It should be remembered in this connexion that the general atmospheric concentration of benzene is by no means an entirely reliable criterion of benzene exposure, since individual workers may at any time be exposed to localized "pockets" of high concentration, particularly when working over open containers.

### Clinical Results

A routine clinical examination, including condition of teeth, throat, lungs, heart, skin, and in many cases blood-pressure readings, was

carried out, and a careful case history taken. The chief points to which attention was paid in the case history were:

1. *Previous Occupation.*—A history of previous exposure to any toxic substance would naturally have to be taken into account in evaluating any disturbance of health or deviation from the normal blood picture. Since many of these women were in the 35-45 age group the previous occupation of a large proportion (about 40%) had been domestic. Among the other occupations represented were clerks, telephonists, waitresses, shop assistants, hairdressers, dressmakers, mill-bands, weavers, and machinists. Only in two cases was there a history of occupation which possibly involved exposure to toxic solvents—one a rubber worker, the other a cleaner of aeroplanes. In both, the blood picture was within normal limits and there were no complaints of ill-health.

2. *Previous Illness.*—No history of previous illness likely to produce haematological disturbance was obtained except "long-standing anaemia" in one case, with a blood picture of mild microcytic hypochromic anaemia only. In 84% of all cases, in fact, no history of illness other than "childish diseases" was elicited; the remaining 16% gave a history of bronchitis (7 cases), tonsillitis (4), appendicitis (3), pneumonia (2), jaundice (1), rheumatic fever (3), heart trouble (2), gastric ulcer (1), gastritis (1), asthma (1).

3. *Symptoms.*—In all, 72 of the 176 women examined (approximately 41%) complained of symptoms probably referable to their occupation. These were in most cases not severe, and were in the following order of frequency:

(a) Lassitude (35).—Many of the women emphasized the fact that their fatigue, especially at night, had been particularly noticeable "since being on this job." It is possible, of course, that this symptom—particularly in women previously engaged in domestic work only, and now doing 47 to 55 hours a week in the factory, with some domestic duties in addition—may be attributed to excessive exertion rather than to benzene absorption; but many of the women appeared to relate their fatigue definitely to their occupation.

(b) Headache (27).

(c) Dizziness (25).—In one factory this symptom took an acute form, 18 women being overcome in one day by what they described as "fainting attacks" and "feeling drunk." Investigation showed that these attacks were very similar to the "benzene intoxication" reported by Kobert (1906) and others, and that the solutions used did in fact contain a high proportion of benzene. A combination of heavy fog, poor ventilation, and intensive production on the day on which this incident occurred was probably responsible for a sudden increase of the benzene content of the air of the workshop.

(d) Nausea (15).—The nausea and vomiting are probably not due to benzene but to other fumes evolved during the process. They seemed to be most pronounced in the mornings, particularly Monday mornings, when the shops had been closed over the week-end, and the fumes from the drying treated articles had accumulated.

(e) Vomiting (4). (f) Dyspnoea (6). (g) Loss of weight (3). (h) Gastric pain (2). (i) Bleeding from the gums not accounted for by local oral conditions (2).

An unusual complaint, for which no satisfactory explanation can at present be given, was that volunteered by several women that the faeces smelt strongly of the rubber solutions used.

4. *Menstrual Disturbance.*—Of these women 45 were between the ages of 40 and 55, and 7 of them complained of menorrhagia; this may probably be attributed to menopausal or pre-menopausal disturbance rather than to a benzene effect. Of the 131 younger women (aged 19 to 39) 4 complained of increased frequency of periods (which may have been associated with the change from domestic to factory life), and only one of recently increased loss. Five women were pregnant, but their health did not seem to be affected.

## Haematological Results

The blood counts of the 200 women working with rubber solution have been analysed and compared with the counts of a group of 200 women, of similar age and conditions of life, who, so far as was known, had never been in contact with rubber solution. The results are shown in the accompanying Chart, in which frequency

Chart showing frequency distribution curves of red cells, white cells, polymorphs, and lymphocytes in the control group (x—x) and the group exposed to fumes of rubber solution (o—o).

distribution curves of the red cells, white cells, polymorphs, and lymphocytes are shown. It was impossible to treat the haemoglobin results in a similar manner, because the method of determining these varied with the conditions obtaining in the different localities where the investigation was pursued, and the methods employed did not all have the same degree of accuracy. This, with the possible variations in the standards used, introduces a degree of error which would render statistical analysis valueless. The differential counts were calculated on a basis of 200 cells where there was no deviation from the normal; 400 were counted in any doubtful case.

In the Chart the mean and its standard deviation for each set of observations are recorded, and from these the probable significance of the difference between means of the red cells, white cells, polymorphs, and lymphocytes of controls and rubber-solution workers can be calculated. If the difference between the means is greater than twice its standard error, then the difference is significant, and the chances are 19 to 1 against such frequency distribution curves being obtained from the same population of cells by random

sampling—i.e., if  $\bar{X}_x - \bar{X}_o > 2 \sqrt{\frac{\sigma_x^2}{N_x} + \frac{\sigma_o^2}{N_o}}$  the difference is significant, where  $\bar{X}_x$  and  $\bar{X}_o$  are the means,  $\sigma_x$  and  $\sigma_o$  their standard deviations, and  $N_x$  and  $N_o$  the numbers of observations in the samples. The daily variations in the various elements of the blood count introduce a possible source of error into comparisons of this

kind, but so far as is possible this has been corrected by taking the counts at the same time of day. However, to allow for this and other errors arising from dilution and counting, we decided not to call a difference between means significant unless it was more than 5 times the standard error of the difference.

The results of these comparisons are shown in Table I, from which it will be seen that significant decreases in the mean values of the total white counts and the polymorphonuclear cells (a decrease in

TABLE I.—Comparison of Blood Counts of 200 Female Controls with those of 200 Females Working with Rubber Solution

	Controls		Rubber-solution Workers		$\bar{X}_x - \bar{X}_o$	
	$\bar{X}_x$	$\sigma_x$	$\bar{X}_o$	$\sigma_o$	$\sqrt{\frac{\sigma_x^2}{N_x} + \frac{\sigma_o^2}{N_o}}$	
R.B.C.	4.581	0.468	4.461	0.342	2.9	Not significant

Polys.	4.672	1.905	3.232	1.130	9+	Not significant
Lymphs.	2.277	0.842	2.375	0.721	1+	

polymorphonuclear leucocytes will hereafter be referred to as "neutropenia") are present in the women working with rubber solution. It will be seen that the standard deviation of the means is always larger in the control group, and this may be because the counts in this group were performed by several persons, whereas in the group being tested all the counts were done by one of us (E. B.). However, the final effect of this is to increase the value of the standard error of the difference between the means and thus decrease the ratio of the difference to the standard error; this will reduce the possibility of getting significant differences and not increase it. The monocytes, eosinophils, and basophils have not been included in this statistical comparison because their numbers are relatively small. Eosinophilia is, however, a recognized feature of the syndrome of severe chronic benzene poisoning.

In considering the individual cases of the test group the following scheme was followed in judging whether the woman should be considered as a possible case of benzene intoxication (Hamilton-Paterson, 1941). A plus sign was given for any of the following abnormalities: Hb below 80% Haldane or its equivalent, with either a macrocytic or microcytic anaemia; white cells below 5,500 per c.m.m.; polymorphs below 3,000 per c.m.m.; eosinophils more than 160 per c.m.m., with a white cell count less than 5,500 per c.m.m.—suggestive symptoms. The presence of three plus signs is suggestive of benzene poisoning, and that of four or more plus values diagnostic in the absence of any obvious causation other than exposure to benzene.

Benzene absorption may of course be present with only one or two plus values, but true benzene poisoning in such a case is rare and is usually accompanied by well-marked clinical signs. The analysis showed that 34 women (17%) were possible cases of benzene poisoning, and that 19 women (9.5%) had four or more plus values and were probable cases; a total of 53 out of 200 (26.5%). The frequency with which the abnormalities occurred in these cases was: neutropenia 50 times, leucopenia 44 times, anaemia 41 times, suggestive symptoms 27 times, and eosinophilia 15 times.

In the second part of the investigation all the women in or factory working with rubber solutions were tested and compared with women in the same factory who had never been in contact with such solutions. In all, 92 subjects were tested—62 contacts and 30 controls. Blood counts on the contacts were done after six months' work with rubber solutions, and those who showed changes suggestive of severe benzene absorption were removed to another part of the factory, where they had no contact with the solutions. After such a "rest" period of three months they again had blood counts to see what improvement, if any, had occurred.

The results are shown in Table II. The numbers involved were too small to compare statistically; averages have therefore been taken and the maxima and minima in each group recorded. It will be seen that the results for the 30 control women agree quite well with the 200 controls in the first part of the investigation. Also, the averages for the 62 contacts are similar to those for the 200 contacts already recorded, except for the red cell count, which is higher than in the control group. The variations in the control and contact groups, as estimated by the maxima and minima, are of the same order. The results in this factory therefore agree well with those of the random samples from the larger number of factories, and, conversely, they suggest that the samples from the other factories closely represent the state of each factory as a whole.

Of the contacts 18 were removed and "rested" because of abnormalities of the blood counts. The averages of this group are shown in Table II, and also their averages at the end of the three months rest period. The difference is striking: the white cell count has increased from 3,680 per c.m.m. to 6,140 per c.m.m., and the polymorphs from 1,750 per c.m.m. to 3,410 per c.m.m. The counts

from showing a gross leucopenia and neutropenia, have returned to within normal limits. These results, indicating recovery from the depressive effect of benzene on the leucopoietic system, are closely comparable with those observed (e.g., Goodfellow, 1935) in radium and x-ray workers. To enhance the value of this observation three

of these women were put back on to the benzene process and again examined in two to four months' time. Their counts are shown in the lower part of Table II, and require but little comment. In each case further contact with rubber solution has led to deterioration of the count.

#### Urinary Sulphates

It has been suggested (Yant *et al.*, 1936) that the determination of the ratio of inorganic to organic sulphate in the urine would be useful in discovering early cases of benzene poisoning. Of the absorbed benzene 90% is excreted in the lungs (Feil, 1933). The remaining 10% is oxidized in the body, conjugated with sulphates in the liver, and excreted in the urine, thus lowering the inorganic/organic urinary sulphate ratio. The lowest normal ratio is about 80/20 (Schrenk *et al.*, 1936; Kammer *et al.*, 1938). Yant *et al.* (1936) state that a decrease in inorganic sulphate in the urine is a constant and early sign of benzene poisoning in animals. A distinct decrease occurred even with conditions of exposure which did not produce anaemia or leucopenia. They suggest that the striking nature and reliability of the change in animals exposed to benzene should serve as a measure of the exposure and potentially harmful conditions in workers, before injury to the organism has occurred. It is emphasized that the changes are merely indicative of exposure and not of poisoning or damage.

Seventeen women with neutropenia, in the factory which was completely surveyed, submitted specimens of urine. The sulphates

were estimated by the method of Peters and van Slyke (1932). All the results were within normal limits: the lowest ratio recorded was 81/19; all the rest were 85/15 or over. Twenty controls similarly examined gave readings ranging between 82/18 and 97/3.

These results would suggest that Yant's findings in animals cannot be applied to man, since in the series recorded here neutropenia certainly preceded urinary changes. In well-marked cases of chronic benzene poisoning the test is useful for confirming the diagnosis, as the inorganic sulphate may fall to below 50% of the total.

#### Discussion

As has been shown in the analysis of the results, the most striking changes in the blood counts are the leucopenia and the neutropenia. These are, of course, well known as the most common changes in the syndrome we call chronic benzene poisoning, before the development of the classical picture of aplastic anaemia, but it can be shown that they may occur in workers who show no clinical abnormality. Out of the 200 women exposed to rubber solutions and examined, 167 (83.5%) had white counts below the mean of 7,422 per c.mm. for the control group; 50.5% of the controls were below this mean. These figures are calculated from the frequency distribution curves (see Chart), and indicate that 33% of the test series have abnormally low white cell counts: 184 (92%) had lower polymorphs than the normal mean of 4,672 per c.mm., 55.5% of the controls being below the mean. Here 36.5% of the test series show an abnormally low polymorph count. In the analysis previously made 53 women (26.5%) of the test series were shown to be either suspicious or definite cases of severe benzene absorption; 44 of the series (22%) were suffering from leucopenia, and 50 (25%) had abnormally low polymorph counts. Thus it is clear that the white cell count has been lowered in 11% and the polymorph count in 11.5% of the test series where there was no indication of benzene poisoning.

It seems obvious, therefore, that there is a definite change in the white cell and polymorph counts before the appearance of other criteria which make a diagnosis of benzene absorption possible. The leucopenia and the low polymorph count run hand-in-hand—33% abnormality in the former and 36.5% in the latter; that is, the leucopenia is directly due to a reduction in the number of polymorphs. This is confirmed by the observation that there is no significant difference in the mean number of lymphocytes in either the test or the control group. The primary change is therefore the reduction in the number of polymorphs. This reduction is reflected in the bone marrow in a case reported by Piney and Hamilton-Patersoo (1943) in which the myelogram showed a reduced percentage of myelocytes and metamyelocytes. To sum up, we may say that the essential change recorded in the test group of women is a neutropenia and that this makes its appearance before there is enough evidence to justify a diagnosis of benzene poisoning.

We have already shown that there is no significant difference between the means of the red cell counts of the exposed and control groups. On the other hand, 41 (20.5%) of the women picked out as possible cases of benzene poisoning showed anaemia—i.e., haemoglobin less than 80% and a colour index outside the limits of 0.85 to 1.10. The probable explanation of this anomaly is the different methods of haemoglobin estimation used—e.g., Haldane, Sahli, an alkaline haematin method (Clegg and King, 1942), and, on some occasions when no other was available, Tallqvist papers. It is possible that many of the results obtained by the last method were unreliable and may have caused us to mark a case as anaemic when in fact no such anaemia existed. It was because of this possible source of error that no attempt was made to compare the haemoglobin results statistically. In severe benzene poisoning, anaemia—either macrocytic and hyperchromic or microcytic and hypochromic—may develop, but the results of this investigation do not suggest that anaemia in any form is a constant early feature of the malady. Iron-deficiency anaemias may be difficult to distinguish from benzene anaemia because they may show a low white count with an abnormally low polymorph count; but administration of iron will probably separate them, because the few cases of benzene anaemia which we have been able to treat in this way have shown no improvement in the haemoglobin percentage and no reticulocytosis.

Eosinophilia has been stressed by some authors, particularly Dimmel (1932-3), as a feature of benzene intoxication. In the present series 18% of the exposed workers and 16% of the controls had more than 160 eosinophils per c.mm., while of the 53 affected workers 14 (26%) showed a similar change. Whitby and Britton (1942) give the normal maximum for eosinophils as 400 per c.mm. This may be so with a relatively high white count; with a white count of less than 5,500 per c.mm. 160 eosinophils should be regarded as the maximum.

Since this investigation has shown neutropenia to be the characteristic change found in early absorption of benzene, an examination of the incidence of neutropenia in the cases showing suspicious symptoms has been made. It may be stated at once that no such consistent relationship exists. Twenty-six (36%) of the 72 women presenting symptoms and 39 (37%) of the 104 symptom-free women had polymorphonuclear counts below 3,000 per c.mm.; that is, neutropenia occurs as often in women without symptoms as in those with them. Again, while three of the lowest polymorph counts recorded (1,600, 1,790, and 1,850 per c.mm.) occurred in three women complaining of more than one symptom—e.g., headache, dizziness, and nausea—even lower values (1,380 and 1,440 per c.mm.) were found in women with no apparent disturbance of health.

Menorrhagia has often been stated to be a leading symptom in chronic benzene poisoning. Eight cases occurred in this investigation, and seven of these were in women between the ages of 40 and 55. Is this menorrhagia due to benzene or to the menopause? As most of the cases occur between the ages of 40 and 55 it would appear at first sight as if the symptom was menopausal; it may be, however, that women at the menopause are more susceptible to benzene poisoning. Menorrhagia, in the absence of malignancy or endometrial abnormality, is a rare complication of the climacteric (Hamblen, 1939). We found 7 out of 43 women (16.2%) of the appropriate age group to be suffering from menorrhagia. This figure of incidence is higher than one would expect from a rare complication, but, as no attempt was made to exclude local disease of the uterus as a cause of the menorrhagia, it cannot be said definitely to be the result of increased susceptibility to benzene; it may, however, be suggestive. It should also be noted that the average polymorph count in these women (3,059 per c.mm.) is lower than in the younger women (3,603 per c.mm.).

There is no agreement in the literature about the subjective symptomatology of the climacteric. Norris (1919) states that 90% of healthy women experience no severe symptomatic disturbance; Hawkinson (1938), however, expressly states that 75% of all women suffer from distressing symptoms during this period. The personal factor is of course difficult to assess. Twenty-four of the 43 women examined (55.8%) complained of one or more of the following symptoms—lassitude, headache, giddiness, and menorrhagia—any of which may have been due to the climacteric or to the absorption of benzene. As this figure falls nicely between the two quoted, it cannot be said to indicate that benzene workers show more disturbance during the menopausal period.

The length of exposure to the fumes of rubber solution ought to be related directly to the neutropenia which has been shown to develop—that is, the longer the exposure the more marked should be the resulting fall in the polymorph count. An attempt was made to demonstrate this with the figures at our disposal, but it appeared that 59% of the women had been exposed for one year or less, and only 13% for a period between 2½ and 3 years. The average polymorph counts for these two groups were 3,163 per c.mm. and 3,445 per c.mm. respectively. As this last figure was calculated from only 26 women it is impossible to say that it presents a true picture of the whole population so employed. If, for argument's sake, it is assumed that the length of exposure does not increase the neutropenia, and therefore does not increase the risk to the worker, it would still have to be shown that the polymorphonuclear count returned to normal with rest after three years' exposure as well as after one year's exposure. Unfortunately all our figures for recovery were obtained on women with only six months' exposure, and at the moment none are available in respect of those with longer exposure.

The figures in the second part of the investigation, dealing with the changes in the blood counts after removal from

exposure to the solution, speak for themselves. After periods of rest up to three months the polymorph and white cell counts have risen and lie within normal limits. In the three women who were again exposed the counts very soon dropped. This observation, taken in conjunction with the previous observation that a lowering of the polymorph count is the earliest and most constant indication of benzene absorption, immediately suggests a method of controlling the absorption—particularly since, as already shown, there is no relation between symptoms and neutropenia. We would suggest that white cell counts should be done on all workers after an initial exposure of, say, six months; and that any who show neutropenia should be transferred to other work and recounts made after two months. If the count is then within normal limits the woman can be put back on her original work for a further period of six months and then be retested. If, however, there is no improvement in the count after the "rest" period the affected woman should be advised to give up work with benzene altogether, as it is possible that her bone marrow may be permanently depressed.

### Conclusion

The toxic effects of the aromatic hydrocarbons (chiefly benzene) used in rubber solutions make the above precautions highly desirable. The substitution of a relatively non-toxic solvent such as solvent naphtha would render haematological control of the worker unnecessary; but so long as benzene is used it is advisable that the persons exposed should be given the protection of routine blood examinations. It may be noted that as the result of representations by the Factory Department the aromatic content of the rubber solutions used in this process has been limited to not more than 5% as one of the preventive measures required.

The question as to how the women with lowered polymorph counts react to infection is obviously important, and is one which we have not enough data as yet to answer. If the injury to the bone marrow is such that it does not recover with rest, it may be that infection will also be an insufficient stimulus to leucocytosis, and the patient thereby be deprived of an important defence mechanism.

The excretion of increased amounts of organic sulphates in the urine is a feature of severe benzene poisoning, but in this investigation no definite changes were found in people who clinically and haematologically showed definite early signs of the malady. It would seem, on the basis of this study, that benzene will produce haematological changes before it is excreted in significant amounts.

### Summary

The clinical and haematological pictures of 200 women working with industrial rubber solutions are compared with 200 control women. Neutropenia is shown to be the commonest and earliest sign of benzene absorption.

It has been shown that there is no correlation between the symptoms complained of and the onset of haematological changes. This is important because clinical examinations alone are probably useless for the specific detection of early cases; but of course they have great value in the diagnosis of cases of deterioration in health due to other causes.

A possible method of preventing the onset of chronic benzene poisoning by regular white cell counts and suitable periods of "rest" is suggested.

# THE SULPHONAMIDES IN OPHTHALMIA NEONATORUM

BY  
ARNOLD SORSBY, M.D., F.R.C.S.

AND  
ELIZABETH L. HOFFA, L.R.C.P.&S.Ed.  
(White Oak (L.C.C.) Hospital)

In an earlier communication (Sorsby, Hoffa, and Smellie, 1942) an account was given of the value of the administration of sulphapyridine in 273 cases of ophthalmia neonatorum treated at White Oak Hospital from towards the end of 1939 till Dec. 31, 1941. By comparison with 46 cases treated by the classical local methods, it was concluded that the results obtained with sulphapyridine justified the description of the new method of treatment as a revolutionary advance and that the classical methods of local therapy no longer had any place in the treatment of ophthalmia neonatorum. It was also shown that sulphapyridine proved as effective in non-gonococcal ophthalmia as in the gonococcal variety. The present paper deals with a further 258 cases (out of a total of 269) seen between Jan. 1, 1942, and Dec. 31, 1943. Of the 258 cases, 133 were treated with sulphapyridine, 43 with sulphathiazole, 28 with sulphamezathine, 31 with sulphadiazine, and in the residual group of 23 more than one of these sulphonamides were used as the cases proved resistant or intolerant to the drug employed initially. The results of treatment are set out in the following table.

TABLE I.—Comparative Results of Some Sulphonamides in Ophthalmia Neonatorum

Clinical Cure	Sulphapyridine			Sulphathiazole			Sulphamezathine			Sulphadiazine			Two or More of these Four			Total		
	Gonococci-positive	Gonococci-negative	Total	Gonococci-positive	Gonococci-negative	Total	Gonococci-positive	Gonococci-negative	Total	Gonococci-positive	Gonococci-negative	Total	Gonococci-positive	Gonococci-negative	Total	Gonococci-positive	Gonococci-negative	Total
1 to 3 days	15 (48.5%)	26 (25.5%)	41 (30.8%)	7	7	14 (32.5%)	3	8	11 (39.3%)	5	5	10 (32.3%)	1	1	2 (4.3%)	31 (51.7%)	46 (23.2%)	77 (29.9%)

\* Including relapses after an apparent clinical cure.

This table confirms the earlier findings as to the efficacy of sulphapyridine both in gonococcal and in non-gonococcal ophthalmia. As was indicated in the earlier study, the results there recorded had to be regarded as an understatement of the value of this drug, for many of the earlier cases received a dosage that later on was recognized as less than the optimum. For this reason it is possible to classify the present data, collected on the basis of uniform dosage, rather more finely than the earlier series: the clinical cures obtained within 8 days are now shown as those achieved within 1 to 3 days and those taking 4 to 8 days. It will be seen from Table I that 85.7% were cured within 8 days (as against 61.9% in the earlier series) and that no fewer than 29.9% were cured within 3 days.

## Relative Value of the Different Sulphonamides

As to the relative value of the various sulphonamides, the only substantial study on the subject has come from Wong (1942), who found that on the average sulphanilamide effected a cure in 7.2 days in 20 cases of gonorrhoeal ophthalmia, while sulphapyridine was effective in 4.8 days in 10 cases and sulphathiazole in 3.4 days in a further series of 10 cases. The results recorded here do not cover a sufficiently large number of cases to allow fine distinctions to be drawn. However, it does not appear that any one of the four sulphonamides studied gives strikingly different end-results. Sulphadiazine has the advantage of being the best-tolerated of these four drugs, and sulphamezathine is probably as good. It is possible—but this requires confirmation—that sulphathiazole, while gratifyingly effective in such cases as respond

to it, is apt to be more selective in effect. Sulphapyridine is probably the least satisfactory owing to its greater tendency towards toxic manifestations; for the present, at any rate, its use as the routine drug has been discontinued.

Though the present series shows more favourable results than the previous one with its many early cases treated before a definite routine had been established, it is of some interest to summarize the findings in these two series, comprising together 531 cases (Table II).

TABLE II.—Results in 531 Cases of Ophthalmia Neonatorum treated by Sulphonamides (273 Cases published earlier and 258 in the Present Series) contrasted with the previously published 46 Control Cases treated locally by the Classical Methods

Clinical Cure	Local Treatment (Classical Methods)			General Sulphonamide Treatment		
	Gonococci-positive	Gonococci-negative	Total	Gonococci-positive	Gonococci-negative	Total
Well in 8 days	2	5	7 (15.2%)	97 (73.0%)	293 (73.6%)	390 (73.4%)
" 9 to 30 days	6	21	27 (58.7%)	26 (19.5%)	96 (24.1%)	122 (23.0%)
" more than 30 days	7	5	12 (26.1%)	10 (7.5%)	9 (2.3%)	19 (3.6%)
Totals	15	31	46	133	398	531

## Gonococcal and Non-gonococcal Cases

In the previous series the incidence of gonococcal infection was 27.3% (89 cases in a consecutive series of 322). In the total present series of 269 cases it constituted 23.8% (64 cases).

The ophthalmia was confined to one eye in 89 instances, or 33.0%—a close approximation to the incidence of 30.5% observed in the previous series. The difference in unilateral incidence as between gonococcal and non-gonococcal ophthalmia is not great, being 28.1% (18 out of 64 cases) in gonococcal ophthalmia and 34.1% (70 out of 205 cases) in non-gonococcal ophthalmia.

The present evidence suggests that, while the sulphonamides are effective in non-gonococcal ophthalmia as well as in ophthalmia due to the gonococcus, rather quicker cures are obtained in the gonococcal variety. Cures within 3 days were obtained in 51.7% of gonococcal cases, against 23.2% in non-gonococcal cases (in 31 out of 60 cases and in 46 out of 198 cases respectively). In both groups the bulk of cases did not require treatment beyond 8 days, 90.0% of all gonococcal cases and 84.3% of all non-gonococcal cases, which included organismal, non-organismal, and the inclusion varieties of ophthalmia neonatorum, having become resolved by that time.

## Delay in Initiating Treatment, and Protracted Cases

As in the earlier series, delay in starting sulphonamide therapy did not affect its efficacy: 85 cases first received sulphonamide treatment after the infection had been established for more than 8 days; these cases responded as well as the 173 less-established infections did. Seven cases had corneal ulcers (all unilateral) on admission. They all cleared quickly and well, leaving hardly perceptible or no scars, and in no case did a corneal ulcer develop while treatment was being given, though a number of infants had hazy cornea on admission.

In cases that take longer than 8 days for cure sulphonamide treatment is generally not needed, as the affection is no longer one of purulent ophthalmia but of a rather resistant conjunctivitis with some muco-pus. The proper treatment of such cases is still a matter of doubt; some, at any rate, are best left alone. In one case (non-gonorrhoeal) profuse purulent discharge continued for nearly a month in spite of intensive treatment with the various sulphonamides. In another, also non-gonococcal, a false membrane formed on the palpebral conjunctiva of the two lids of one eye, and is disappearing only now, three months later; all active treatment was suspended at the end of the first month, and at no time was there any apparent danger to the cornea.

Few relapses have been seen in the present series, and this is perhaps due to the greater initial dosage (0.25 g.) and maintenance dosages of 0.125 g. four-hourly, not only during the active phase of the affection but for three days after apparent clinical cure. Apart from minor toxic effects no untoward results were observed.

### Causal Organisms

The 198 non-gonococcal cases in the present sulphonamide series included 50 in which pus cells only, but no organisms, were found, 52 with various bacilli (mostly diphtheroids), 88 with staphylococci, and 8 with other coecal organisms. Inclusion bodies were found 27 times; they occurred twice in association with organisms and 25 times in cases in which no organisms could be found. The actual distribution of the various organisms in this series, taken together with the 11 cases not treated by sulphonamides (but by newer methods of local therapy), is shown in Table III, which includes comparative figures from the previous series.

TABLE III.—Differential Incidence of Organisms in 269 Consecutive Cases of Ophthalmia Neonatorum treated in the Period Jan. 1 1942, to Dec. 31, 1943, with Comparative Findings for 322 Cases seen during Sept., 1939, to Dec., 1941

	Sept., '39, to Dec., '41	Jan., '42, to Dec., '43	Total

Total	322	269*	591

\* Inclusion bodies found 27 times: twice in association with organisms and 25 times without organisms.

### Summary

In the earlier series of 273 cases of ophthalmia neonatorum treated by the oral administration of sulphapyridine, 61.9% showed clinical cure within 8 days.

In the present series, in which a standard dosage was used in 258 cases, 133 were treated with sulphapyridine, 43 with sulphathiazole, 28 with sulphamezathine, and 31 with sulphadiazine; two or more sulphonamides were used in the remaining 23 cases, which were either resistant or intolerant to the sulphonamide used initially. In these 258 cases clinical cure was obtained within 8 days in 85.7%.

A high proportion of cases (29.9%) showed clinical cure within 3 days; 55.8% required from 4 to 8 days for clinical cure; and 14.3% showed a protracted course.

There was no appreciable difference in the action of the four sulphonamides used. Clinical cures within 8 days were obtained in 88.7% of cases treated with sulphapyridine, 93.0% of those treated with sulphathiazole, 92.9% of sulphamezathine cases, and 83.9% of

sulphadiazine cases. Sulphapyridine, because of its greater toxicity, appears to be the least desirable of these sulphonamides.

Gonococcal cases responded more rapidly to sulphonamide therapy than did the non-gonococcal cases; 51.7% of the 60 gonococcal cases showed clinical cure within 3 days, against 23.2% of the non-gonococcal cases. By the end of 8 days 90.0% of all gonococcal cases and 84.3% of non-gonococcal cases were clear.

In the present series inclusion bodies were found in 27 instances: twice in association with organisms and 25 times without such association. These cases responded well to sulphonamide therapy.

Only exceptionally is a case completely resistant to sulphonamide therapy. It is more a matter of sluggish response than of total resistance.

The routine at White Oak Hospital now includes administration of the sulphonamides for 3 days after clinical cure; fewer relapses are now observed.

We are indebted to Dr. E. N. Young of the Southern Group (L.C.C.) Laboratories for her painstaking bacteriological examinations. We are also obliged to Dr. G. Heister, and to the Matron and Sister Condon of White Oak Hospital, for their collaboration.

## THE BLOOD PRESSURE IN MIDWIFERY

BY

WALTER RADCLIFFE, M.B., B.Chir.

A study of the blood pressure during the later months of pregnancy is a recognized part of adequate ante-natal care, yet often it is neglected as soon as labour begins. This is all the more surprising since the value of blood-pressure records has been well established on the operation table and in the prevention and treatment of traumatic shock, and the same influences—drugs, haemorrhage, and trauma—are present to some extent in most labours.

The literature on this subject is very scanty; the most useful articles in the English language are those by Cook and Brigg (1903), Bailey (1911), Donaldson (1913), Schwarz (1923), Simon and Rasmussen (1925), and Matthews (1939). The subject is also practically ignored, apart from mentioning the blood pressure in eclampsia and toxæmia, in all the recent textbooks on midwifery that I have seen.

I have made records of the blood pressure, both systolic and diastolic, in all my midwifery for over two years, and I find them very instructive in assessing the effects of management and treatment, especially analgesia and anaesthesia. The technique is simple and well within the scope of the general practitioner, even when working alone. The chief difficulty arises when the doctor is distracted from the mother to attend to urgent foetal asphyxia, for it is at this time during the third stage of the labour that the most important changes in blood pressure take place. I firmly believe that, if more attention were paid to the blood pressure incipient shock would be recognized earlier while still amenable to simple treatment, and the lives of many of our mothers would be saved.

### Types of Blood-pressure Curve

The first problem to be solved is that of the normal—that is to say, the blood-pressure curve in a straightforward delivery uninfluenced in any way by drugs or obstetric manipulations. It has been stated by Halls Dally (1936) that "during labour there is a progressive elevation of blood pressure, even to considerable heights as the pains become more intense, reaching a maximum as the head of the infant is expelled. After delivery the pressure rapidly falls." In my experience this description is very misleading, and there is far less disturbance of blood pressure than one would suppose.

Graph A is a typical blood-pressure curve, and probably approximates to the normal, even though nitrous oxide analgesia was given towards the end of the second stage. Exactly similar curves are recorded when no form of analgesia is given, and also when the agent used is weak chloroform or trichlorethylene. I will be seen that in labour there is a rise of about 20 mm. H followed by a short-lived fall after delivery, partly due to reduced pulse pressure, but also shown in the diastolic pressure as well. This particular case the blood pressure as the head was being born was not recorded, but I have rarely found it much higher.

after delivery the blood pressure rises again, and this coincides with the return of uterine contractions. After the first day there is a gradual fall during the puerperium, but Donaldson (1913) has pointed out that this fall is no more than one would expect to find in any patient who was confined to bed.

I have recorded not only the systolic pressure but also the diastolic, and no account has been taken of the rise in pressure during pains, the recorded figures being taken only between each contraction. Although it may not be strictly accurate, I have assumed for all

delivery is also negligible, but soon afterwards there is a sharp increase in the pulse pressure. In my experience such an increased pulse pressure soon after delivery invariably coincides with a sharp bout of shivering. This is an observation which, so far as I am aware, has not previously been made, but I think it is of considerable importance in explaining the changes which take place in the third stage of labour.

A theory has been handed down from the time of William Smellie that the sudden emptying of the uterus at birth tends to cause

GRAPH A.—Primipara aged 23. Labour Feb. 26-27, 1942. R.O.P. rotating spontaneously to R.O.A. Dry labour. No drugs given other than  $N_2O + O_2$ . Full-term male child, 6½ lb.

GRAPH B.—Primipara aged 23. Labour Dec. 26-27, 1941. Persistent R.O.P. Full-term female child, 7 lb.

practical purposes that the diastolic pressure is a measure of the peripheral resistance to the circulation, and therefore an index of the vasomotor tone, and that the systolic pressure represents the sum of this peripheral resistance plus the pulse pressure, representing cardiac output. In studying these records I would stress the value of the diastolic pressure, and point out that the systolic pressure alone tells us only part of the story.

Graph B is a second type of blood-pressure curve, and is nearly as common as the first example. In this type there is very little or no increase in the blood pressure during labour, and the fall after

collapse. His pupil, John Harvie (1762), described it as "too great quantity of blood rushing into ye relaxed vessels of ye abdominal contents, whereby ye head is robbed of its due proportion, and dangerous faintings ensue." This phenomenon was thought comparable with the collapse which sometimes follows paracentesis abdominis. To it has been attributed not only obstetric shock but also the fall in systolic pressure (Cook and Briggs, 1903) and the shivering bout (Phillips, 1931). It is interesting to note that the splanchnic pool theory of shock has only recently been discarded. Bailey (1911) was the first to doubt the theory, and suggested that

Graph E affords, a marked contrast, for although there was a small post-partum haemorrhage, the picture was completely overshadowed by shock, shown by faintness, giddiness, and a cold perspiration, and a very severe drop in both the systolic and the diastolic pressure to 80/60 mm. Hg, which is within the limits described by Hewer (1943) as critical hypotension. Fortunately energetic treatment brought about a prompt recovery. A point of practical importance arises in such cases; it will be seen that no attempt to repair the perineum was made until the blood pressure had been restored to normal limits, and then a local anaesthetic was used in preference to a general one rather than run any risk of upsetting the vasomotor balance again. It has been pointed out by Miles Phillips (1931) that even the small amount of trauma caused

Apart from example C, in which a mild degree of toxæmia before labour is shown to have responded rapidly to treatment, I have

A valuable clinical lesson which may be learnt from these records is the depressant effect of drugs used for analgesia and anaesthesia. The barbiturates are the worst offenders, and a drop of 20 mm. Hg, both systolic and diastolic, is commonly recorded after the normal doses. Graph C is an example of such a fall after the use of nembutal, and I have seen just the same after seconal. This graph, in addition, shows well the effect of prolonging ether anaesthesia, given in the first place for low forceps, through the third stage of labour to cover a small perineal repair operation. While it is well known that chloroform anaesthesia produces such hypotension, it is not always realized that ether does so too once the initial stimulant effect has passed off. The importance of hypotension under anaesthesia as a precursor of shock has recently been stressed in an article by Dodd and Prescott (1943). If such hypotension can be demonstrated in the mother, what must be the effect on the foetal circulation? Among the causes of foetal asphyxia anaesthetics and analgesic drugs administered to the mother play a very considerable part (Shaw, 1943). One is justified, I think, in assuming that any depression of the maternal circulation must be reflected in that of the foetus, at least up to the moment when independent respiration begins. Further research along these lines might lead to a reduction in the stillbirth rate.

given no examples of the blood-pressure changes in toxic cases. I consider myself fortunate in not having seen an eclamptic fit in twelve years of practice. This aspect of the subject is fairly well covered in the literature, especially in papers by Hirst (1910), Bailey (1911), Bailey and Driscoll (1926), and Adair, Hunt, and Arnell (1936). The last-named authors have been so impressed by the grave danger of shock in toxic elderly multiparae that they have coined the very graphic expression "vascular collapse" for this association.

# Conclusion

There are thus many practical lessons to be learnt even from my short series of about 40 cases. Obviously, since they produce such marked hypotension, the barbiturate drugs should be used only in the early stages of labour, and are best avoided within a short time of delivery. Also any hypotension which may be present during the third stage of labour is to be

GRAPH D.—Para-1 aged 34. Labour Sept. 28-29, 1942. L.O.A. Full-term male child, 7½ lb. Post-partum haemorrhage.

GRAPH E.—Primipara aged 26. Labour Dec. 28-30, 1942. L.O.A. N<sub>2</sub>O + air + trichlorethylene. Full-term male child, 6½ lb. Small p.p.h. Later developed phlegmasia alba dolens.

regarded as a danger sign, and the blood pressure should be restored before anything else is done, the only exception to this rule being the minimum steps necessary to stop haemorrhage. It is not always appreciated that in cases of traumatic shock the precipitating injury precedes the secondary factors, such as pain, exhaustion, drug depression, and injudicious rough handling, which join in to complete the clinical picture; whereas in labour most of these factors will have been present for some hours before the final trauma which determines and initiates shock. The ultimate state of shock is the same, but the sequence is different. When, therefore, a long and difficult labour is anticipated we have a particularly favourable opportunity of controlling these accessory factors, especially if we study the blood pressure.

I would therefore urge the general practitioner to use his sphygmomanometer at the bedside in his midwifery, and cannot do better than quote in support of my plea the words of Prof. Miles Phillips (1936), who made it his practice to do so, although he has not published his figures. Speaking before an American Association of Surgeons, he said: "Neither she nor her husband was concerned with the maternal mortality rate—only four, five, or six in a thousand—but they did expect you to take every precaution."

May I record my thanks to Mr. Shields, librarian of the British Medical Association, for his indefatigable help in supplying me with the available references.

## NERVOUS BREAKDOWN IN THE NAVY DOMESTIC DIFFICULTIES AS A CAUSAL FACTOR

BY

GEOFFREY TOOTH, M.B., B.Ch., D.P.M.

Temp. Surg. Lieut.-Cmdr. R.N.V.R.; Neuropsychiatric Specialist;  
late Assistant Medical Officer at the Maudsley Hospital

While it is generally agreed that prolonged psychotherapy has no place in the treatment of psychiatric casualties in the Services in wartime, this need not mean that the psychiatrist should concern himself only with diagnosis and institutional efforts at rehabilitation. In this paper the part played by the domestic affairs of the sailor in determining the onset and gravity of nervous breakdown is considered and suggestions are made for investigating and treating these difficulties more effectively. Psychological motivation is said (Kretschmer, 1934) to be due to combinations of causes, of which the least socially and morally acceptable possesses the greatest driving force and is furthest removed from consciousness, whereas that which the patient considers to be the most easily acceptable is in the forefront of consciousness and is the manifest cause of any reaction. Wartime propaganda is directed towards assigning to patriotism and devotion to duty the highest ethical values and stressing the subordination of the individual and the family to the State. In this present struggle, waged by conscript armies and navies, such a fundamental change of outlook might well give rise to conflicts, of which the most potent cause need not be the most obvious.

### Actiological Classification of Naval Psychiatric Material

In classifying the causal factors in mental illness it is usual to make a broad distinction between those that are determined mainly by the personality of the patient and those that are chiefly environmental. Though it is seldom possible to make a

rigid distinction between endogenous and exogenous, yet for purposes of treatment and prognosis it is almost essential to divide the facts of the history in this way. Exogenous factor can be considered as forming a graded series, the members of which will vary in their closeness to the centre of the patient's personality. On theoretical grounds it would be reasonable to assume that those factors which most intimately affect this hypothetical nodal point of the personality would have the greatest strength in causing a nervous breakdown: the effect of domestic trouble are explicable on this basis.

Wartime psychiatry is greatly simplified because the individual environmental stresses in war are much more constant than they are likely to be in peacetime; for example, the living conditions of a sailor in his ship, which may be his home for years at a stretch, are so invariable as to be comparable to those artificially produced in a psychological laboratory. The effects of stress are evenly distributed throughout the ship's company, and, although there are differences in responsibility among the various ranks and ratings, so far as exposure to what are usually termed "the hazards of life afloat" are concerned all can truly be said to be in the same boat. The realization of this has led to the conception that the breakdown of a small percentage of a ship's company following an action is an indication of the poor morale of those who succumbed, and because the majority stood up to the test, cannot be attributed to the conditions of the action. In some cases this may be true but it is probable that this assumption accounts for only a small number of the men who break down under the stress of action.

On the basis of the observation of fairly large numbers of these cases, it appears more likely that unfavourable reactions to stress are due, in order of frequency, to the following causes: (1) constitutional weakness of the personality; (2) combinations of environmental factors; (3) simple bad morale, in the sense of "yellowness" or lowered social responsibility. It is with the second of these groups that this paper is chiefly concerned.

### Effects of Stress

By the time a man becomes a frank psychiatric casualty, unless he belongs to the low-morale group, he has usually had to readjust or repress his former scale of ethical values, and the ease with which he does this depends upon his personality. Both in the last war and in this it has been noted (Beaton, in *The Naval Medical History of the War*; Curran and Mallinson, 1941) that the better types suffer affective changes in the direction of either depression or elation, usually combined with anxiety, whereas their less meritorious messmates react with hysterical symptoms. It has been observed, moreover, that affective disturbances in good personalities, when they are due to the effects of war service uncomplicated by other factors, respond surprisingly well to ordinary hospital conditions. It is those cases in which the causal factors are multiple that sometimes present unusual clinical states and, on the whole, do badly. In the Services, the return of a man to duty is a fair measure of the success of treatment; invaliding usually implies failure, and the invaliding rate may be regarded as an indicator of the virulence of a condition.

In the Navy there appear to be two groups of exogenous factors, which are not directly connected with the hazards of war: (a) the conditions and type of service, including reactions to authority, disappointments over promotion or the lack of official recognition of services, and other specifically Naval determinants; (b) domestic difficulties. Of these two groups the former is the commoner; but the latter, as will be shown, can give rise to the most virulent and intractable reactions, leading to invaliding in a high proportion of cases.

The home life of the sailor has been the subject of ribaldry and a cause of unhappiness for as far back as the lives of seagoing men are recorded. Among sea-faring peoples the subject has become part of the national mythology; it is not recorded that Jason or Ulysses suffered from anxiety states, but their behaviour on landing after long voyages showed considerable apprehension as to what might have happened at home in their absence, and the Norse sagas abound with references to these additional hazards of sea life. The Admiralty has evidently given much thought to this matter, and in peacetime every effort is made to enable the sailor to lead a double life with the minimum of discomfort and disruption of his material home.

But in wartime, although opportunities for reunion with the family are given whenever possible, many men must be separated from their homes for long periods. It is hardly surprising that such unusual conditions should sometimes lead to difficulties. I have had the opportunity of observing the results of these factors under two widely different conditions—for the first eighteen months of the war on the South Atlantic station, and for the past two years in a Naval hospital at home.

The total number of cases seen during the first period was too small to be of use for statistical analysis, but those seen during 1942 are given in the following table. In order to reduce any effect due to personal bias the figures are taken from the returns of two separate Naval hospitals and represent the combined opinions of at least five different psychiatrists. Only those cases are included in which the aetiological factors were quite definite, and these form, of course, a small proportion of the total number seen during the year.

Number of Cases during 1942

Aetiological Factor	Returned to Duty	Invalided	Proportion Invalided
Domestic difficulties ..	58	32	35.6%
Enemy action (E) ..	137	56	29.0%
Conditions of service (C)	89	26	22.6%
Total .. ..	284	114	28.6%

It will be seen from these figures that the percentage of men invalided from the group in which domestic trouble was the main causal factor is higher than in the other groups. The difference is not quite significant. Bearing in mind that a man is not invalided on compassionate grounds but because he shows symptoms of mental illness and is medically unfit for further service afloat or ashore, even though he may be in part responsible for his home difficulties, it is clear that domestic worry is at least as effective a factor as exposure to enemy action in causing breakdown leading to invaliding.

Where two or more factors, of which one is domestic trouble, are combined, the virulence of the reaction is considerably higher than when domestic worries alone are responsible. The following table illustrates this point, and the difference between the groups is significant, although the numbers are small.

Aetiological Factor	Returned to Duty	Invalided	Proportion Invalided
Domestic difficulties alone ..	37	12	24.4%
Domestic + E or C ..	21	20	45.7%
Total .. ..	58	32	35.6%

Although this observation might appear to be self-evident, it helps to explain some puzzling clinical pictures. It is a common experience for men to be sent into hospital with a psychiatric diagnosis and a history of exposure to enemy action which may be more or less recent; the history points to war experience as the cause of their breakdown, and the patient is often content, for various reasons, to allow it to be thought that this is the whole story. It is only after the condition has failed to respond to the usual treatment that a more thorough investigation and the interviewing of relatives reveal a sometimes long-standing anxiety over domestic affairs, to which war service has merely served as a catalyst in precipitating a psychopathological reaction.

The early recognition of the cause is of some importance both for treatment and in the assessment of attributability; for in these cases, if war service alone is considered responsible, the patient may become eligible for a pension. The following record illustrates this type of case:

*Case 1.*—A stoker petty officer, aged 32, with a previously stable personality and a clear record of twelve years' Naval service, had been abroad since Dec., 1940. He had been involved in the evacuation of Greece and Crete, and was subsequently employed in running supplies to Tobruk until Nov., 1941. He stood up to this long and continuous spell of hazardous work without feeling any ill effects, and carried on until Nov., 1942, when, following the loss of some merchantmen in the convoy his ship was escorting, he broke down and was admitted to hospital in Jan., 1943. On examination he was very depressed and agitated, and blamed the long spell of sea service for his condition. He made no mention of home worries, but in

an interview with his sister the following facts came to light. In 1939 he had married against the wishes of his family, and was very devoted to his wife, who during the time he had been abroad had been sharing a flat with her sister, of whom the patient did not approve. Towards the end of 1941 she had written asking his permission to adopt the alleged illegitimate son of this sister by a foreign sailor, and to this the patient raised no objection. There was a hitch in the adoption proceedings when the man who had been, unbeknown to himself, cited as the father of the child proposed to the alleged mother and was accepted by her. As this might have led to a difficult family situation, fresh adoption papers had to be taken out and the name of another man given as the father. It was at this stage of the proceedings that the patient returned home, and, although he gave no indication of suspecting his wife of double-dealing, there was no doubt from his letters to her that he was extremely worried about the whole affair. The true facts, as attested by the patient's sister, were that the child was born to the patient's wife during his absence.

A welfare society was supplied with the facts of the case but took no action, which, considering the complexity and delicacy of the situation, was hardly surprising. At no time could the problem of the parentage of the child be discussed with the patient or his wife, but, no doubt relieved by the prospect of going home for good, he improved sufficiently to be discharged from hospital, and was invalided.

It is possible that, as the result of his war experience, this man would have broken down in any case, but it seems more likely that the sense of insecurity and anxiety over his home affairs was the primary factor and that the war experience served as a face-saving device. His reticence and his unwillingness to face up to the realities of the domestic situation, of which he could hardly have been unaware, support this view.

#### Types of Domestic Trouble

An analysis of the types of domestic trouble that have led to breakdown shows that the real or suspected infidelity of a wife or fiancée heads the list by a clear margin, followed by the illness or death of near relatives, including the prospect of childbirth; financial stress and the more concrete situational problems appear to give little trouble. In this connexion it was observed that out of the 42 patients whose breakdown was attributed to domestic factors during the eighteen months from Jan., 1940, to July, 1941, on the South Atlantic station, anxiety due to enemy action at home was given by only one as the cause of his condition. This period includes, of course, the time during which the "blitz" of England was at its height. To explain this curious fact on the basis of "out of sight, out of mind" would probably be incorrect; it seems more likely that an anxiety shared by many is easier to bear and its virulence is in inverse proportion to the numbers who have to put up with it. This is possibly analogous to the rarity with which sea-sickness, from which so many of the sea-going population suffer, is given as the primary factor in breakdown. It also appears to be easier to accept philosophically the personal share of a common disaster when it is at a great distance than when, as in the case of home-based personnel, it is spatially close to them. Again, the relatively lower virulence of the effect of enemy action is probably due to the fact that it is rarely a solitary experience, and morale can therefore be built up against it. By contrast with these communal stresses, which may be said to affect only the periphery of the personality, the infidelity of a wife affects the husband's self-esteem and is aimed at its very centre.

#### The Need for Thorough Investigation

The record below illustrates the difficulties that may be encountered in the investigation of a case of this kind:

*Case 2.*—A South African stoker, aged 35, was admitted to hospital ship for the investigation of an intractable dyspepsia, which rendered him useless for duty. No organic abnormality was discovered, but the patient stated that he was very worried about the behaviour of his wife, who, he alleged, was living with another man, squandering his money, and neglecting his home and child. His story, which had some documentary support, was vouched for by the captain of his ship, who had already given him a spell of compassionate leave on the same grounds. On the strength of a recommendation backed by his commanding officer, the Commander-in-Chief granted a further period of leave to enable him to divorce his wife and arrange for the care of his child. On his arrival in Capetown, investigation by the chaplain at the base failed to confirm the man's story, and his subsequent desertion made it probable that the whole tale was a tissue of lies.

This case is instructive in showing the necessity for thorough social investigation, and also because it demonstrates how misguided would have been the alternative measure of invaliding such a man on the grounds of his dyspepsia.

#### Methods of Investigation

The inquiry into the circumstances and the treatment of such cases is by no means easy; under the existing system the divisional officer is responsible to his captain for the individual welfare of his men; this responsibility is shared to some extent by the chaplain in a big ship or at a shore base. That more men do not go sick from this cause under the exacting conditions of Naval service is a tribute to the efficiency of the system as much as to the stability of the men themselves. The introduction of airgraph letters and cheap cable rates has undoubtedly done much towards allaying the anxiety of men on foreign stations; nevertheless there does seem to be a need for a more specialized branch of social welfare organization to which complex and difficult cases could be referred, especially by the psychiatric specialists in depots, where such cases are usually first seen.

Much can be done, and is being done, by the existing welfare societies, but, since in peacetime it has been found necessary to employ specially trained workers in this field, the need can scarcely be less great in wartime. It is sometimes objected that the Englishman will not tolerate interference in his private affairs, but this prejudice is not borne out by personal experience or by the records of the psychiatric social services. The epic success of a follow-up of 100 families in which both parents had committed suicide marks a high level of achievement, and is a tribute to the workers who carried it out without a single rebuff. The growing demand for trained psychiatric social workers in clinics and voluntary hospitals is an indication that this kind of work is needed and can be effective.

It is possible that a further expansion of the social services—as, for example, by the appointment of a psychiatric social worker to Naval depots—might lead to a reduction in the invaliding rate from this cause. The work of the psychiatrists in hospitals and barracks would be greatly helped by such an arrangement, and it seems possible that the executive branch might also welcome assistance in carrying out what must be a difficult and time-consuming part of their duties.

#### Summary

The role of domestic difficulties in causing nervous breakdown in the Navy is compared with that of other aetiological factors; special note is made of the bad prognosis in these cases and in those in which there are multiple causal factors. The various types of home worry and the possible causes of its virulence are discussed. The need for thorough investigation is illustrated, and a suggestion is put forward for the enlistment of the services of psychiatric social workers to supplement the existing arrangements.

## THE TONIC ACTION OF STRYCHNINE

BY

W. F. ANDERSON, M.D.

(From the Department of Materia Medica and Therapeutics,  
University of Glasgow, and Stobhill Hospital, Glasgow)

Strychnine is often used as the principal constituent of tonic mixtures. This custom is in part dependent on the belief that in therapeutic doses this drug has a beneficial action on the gastro-intestinal tract, promoting the appetite, rendering the digestive processes more efficient, and thereby increasing weight and general well-being. Strychnine, of course, in virtue of its taste has the action associated with simple bitters which reflexly increases the appetite and the flow of gastric juice. Therefore, in order to determine whether strychnine has any effects other than those due to the taste the drug should be given parenterally.

#### Experimental Findings

The present research was carried out with the view of finding whether strychnine administered parenterally had any action on

gastric digestion and whether any evidence could be obtained in support of its use as a tonic.

*Effect of a Single Dose of Strychnine on the Secretion of the Fasting Stomach.*—Four specimens of fasting juice were aspirated at 15-minute intervals. Thereafter 1/20 gr. of strychnine was injected subcutaneously and the juice again withdrawn during the succeeding hour. In four subjects with normal gastric acidity there was an increase both in the volume and in the hydrochloric acid content of the gastric juice after administration of the drug. In three patients with achlorhydria the strychnine failed to stimulate the secretion of hydrochloric acid or to alter significantly the volume of the secretion.

*Effect of a Single Dose of Strychnine on the Movements of the Fasting Stomach.*—Bennett (1923) stated that small doses of strychnine had a beneficial effect on gastric atony, and quoted Berti to show that as small a dose as 0.5 mg., given orally, caused increased gastric peristalsis. Dickson and Wilson (1925) also maintained that strychnine increases gastric motility. Bastedo (1936) stated that it increased the height of the hunger contractions. Clark (1940), on the other hand, affirmed that strychnine had no effect on gastric movements even when given in large doses. In the present investigation 1/20 gr. of strychnine hydrochloride was given after a period of at least five hours without food or water. Gastric motility was recorded by a modification of Carlson's balloon method (Anderson, 1943). In eight subjects the strychnine was given during a period of quiescence, and in each of them strong gastric contractions appeared after an interval of 5 to 15 minutes, and lasted from 20 to 45 minutes. The movements so produced were strong, and the interval between each wave tended to become shorter towards the end of the period of contractions. In two subjects the strychnine was given after a period of contractions had lasted 35 and 45 minutes respectively; in each case a prolonged period of quiescence followed the administration of the drug. The quiescent phase may have been due to fatigue of the gastric muscle.

*Effect of Continued Administration of Strychnine on the Response of the Gastric Secretions to a Test Meal.*—The subjects of this investigation were 2 men with a slight degree of hyperchlorhydria and 5 with achlorhydria. Strychnine hydrochloride gr. 1/30 was given subcutaneously three times daily for three to four weeks. Test meals were given before and at the end of the period of strychnine medication. In one patient with hyperchlorhydria the maximum percentage of hydrochloric acid was reduced, while in one achlorhydric a small amount of free hydrochloric acid appeared. In no other patient was there any significant change in the secretion of acid. In four subjects the emptying-time was shortened, while in the other three it was unaltered.

*Effect of Subcutaneous Administration of Strychnine on the Weight and General Condition.*—Ten patients convalescing from various types of illness were employed for this investigation. In all, the weight had been stationary for three weeks before the drug was given. In addition the haemoglobin had been estimated together with the red and white cell counts. The strychnine was given subcutaneously in doses of 2.9 mg. three times daily for periods of 14 to 28 days. All the patients were on full ward diet and were all encouraged to eat as much as they desired. There were no significant changes in either the haemoglobin percentage or the cell content of the blood. Five patients showed an increase in weight of 1 to 5 lb., while in three patients there was a decrease of 1 lb. and in two there was no alteration.

*Effect of a Single Injection of 1/20 gr. of Strychnine on the White Blood Cells.*—Sollmann (1936) states that *in vitro* phagocytosis is hindered by very large doses of strychnine, while Edmunds and Lloyd (1923) find an increase in the white cells in healthy dogs. In two patients who received a subcutaneous injection of 1/20 gr. of strychnine no significant change in the number or distribution of white cells was noted.

#### Summary

From these investigations on strychnine three positive findings emerge: this drug appears, first, to stimulate the fasting stomach to active contractions; secondly, in some cases to hasten the emptying-time after a test meal; and, thirdly, to increase the volume and acidity of the fasting gastric juice. No evidence has been here

adduced to indicate that the parenteral administration of strychnine leads to any improvement in the general condition of the patient.

I should like to express my indebtedness to Prof. Noah Morris for his help, and to the Medical Research Council for a grant towards expenses.

## Medical Memoranda

### Mechanical-lung Treatment of Pneumonia complicating Acute Poliomyelitis

The following case is reported because of the excellent results obtained by using the mechanical lung in the treatment of pneumonia in a patient who was almost moribund.

## CASE HISTORY

The patient was admitted to hospital on Aug. 22, 1943, as a transfer from another hospital. His history up to that time is described from the notes which accompanied him and from his own observations.

On the morning of Aug. 20 the patient, a warrant officer aged 25, reported sick with a severe headache. By evening his headache was very bad, he had developed pains in the back, and he felt feverish. On admission to hospital he was found to have coarse rhonchi in the left base of the chest and also a few rales; there was no dullness. He was ordered sulphapyridine 2 g., four hours later 2 g., and then 1 g. four-hourly. The next morning he complained of pain in the back, pains down the front of his thighs, and weakness. His eyes were suffused. By evening the signs in his chest had subsided and he was taken off sulphapyridine, having received 8 g. Headache was slight at the time and he had no bodily pains. In the afternoon he had attempted to get out of bed, but found he could not do so, although he could sit up. Next morning he could neither sit up nor move his lower limbs. Knee- and ankle-jerks and superficial abdominal reflexes were absent. He was transferred to this hospital as a case of acute anterior poliomyelitis.

Aug. 22.—Examination showed a young man of anxious expression and very apprehensive, well nourished, and well developed; his face was a little cyanosed. At 2 p.m. his temperature was 101°, pulse 60, and respirations 26; breathing was entirely diaphragmatic. Abnormalities in muscle power and reflexes were: left and right biceps and right serratus magnus flaccid; deltoids moderately strong; pectorals and biceps strong; biceps reflexes brisk; intercostals and abdominal muscles flaccid; superficial abdominal reflexes absent; back and buttock muscles flaccid; thighs flaccid; knee-jerks absent; slight power in left gastrocnemius, right flaccid; ankle-jerks absent; moderate power in left tibialis anticus and peronei; slight power in right anticus and peronei; plantar reflexes flexor. Muscles were not tender, and there were no abnormalities of sensation. Paresis of the bladder was present, and the sphincters were continent. His white cell count was 10,800 per c.mm.—polymorphonuclear, 82%. The cerebrospinal fluid contained increased globulin, 15 cells per c.mm.—polymorphs—and was sterile. The only other finding was diminished breath sounds at the right base, posteriorly.

Aug. 23.—T. at 6 a.m. 101.6°. Catheterized twice; vomited twice.

Aug. 24.—T. 99.4°. P. 70. R. 24 at 10 a.m. Was more cyanosed. Percussion note dull at right base posteriorly and V.P. increased. Breath sounds faint over right posterior lower third of chest; no adventitious sounds. Apex beat not displaced. Partial collapse of right lower lobe—liver's interference with diaphragmatic action considered the probable cause. The head of the bed was raised.

Aug. 25.—T. 102.8°. P. 86. R. 36 at 6 a.m. Further cyanosed. Chest signs unchanged. Radiograph of chest showed opacity of irregular density of right lower third, with some mottling of middle third and increased right hilar shadows. Lobar pneumonia, right lower lobe, diagnosed. Fowler position adopted and 2 g. of sulphathiazole given, to be followed by 1 g. four-hourly.

Aug. 26.—T. 99°. P. 100. R. 36 at 6 a.m. At 6 p.m. his general condition was worse and he looked a bad colour. Bubbling rales could be heard at some distance and he was unable to cough. Some viscid sputum from time to time collected at the back of his throat and was swallowed out of his mouth. When passing through the larynx it caused considerable respiratory distress, and on two occasions he vomited, bringing up sputum. Respirations 46, shallow and jerky. Oxygen given by nasal catheter. At 11 p.m. was mildly delirious and looked gravely ill.

Aug. 27.—At 2 a.m. he was delirious and ashen in colour. There were loud bubbling rales, and a rattle in his throat. P. 140. R. 44. He was placed in the mechanical lung, head end raised on 9-in. blocks. (The respirator had been completed by the Military Engineering Service only three hours earlier, they having done the job in a

day.) At 5 a.m. there was a dramatic improvement. Cyanosis was slight, pulse 92, and orientation normal, though the patient was apprehensive of the lung and wanted to be taken out. Breathing was quiet and no rales could be heard. The lung was working at 25 respirations a minute and at pressures of -4 cm. H<sub>2</sub>O, +4 cm. H<sub>2</sub>O. At 8 a.m. the patient was removed from the lung to be catheterized and made comfortable. R. 36. P. 116 after 10 minutes, and cyanosis returning. Replaced in lung after half an hour, and pulse soon settled to 96 a minute.

From this time on he made good progress and finally left the mechanical lung on Sept. 8. On Oct. 1 his paralysis remained much as on admission, except that the upper-arm muscles were much weaker. His bladder function returned on Sept. 1.

The striking effect of the mechanical lung was the change it produced in the chest—from a "bubbling cauldron" to quiet breathing; for no rales were audible after 8 a.m. on Aug. 27.

In am indebted to Col C. H. N. Baker, Officer Commanding, for permission to publish this case.

### Tuberculous Infection of an Extrapleural Pneumothorax complicated by *Cl. welchii* Infection

It may be of interest to record a case of pulmonary tuberculosis in which a tuberculous effusion in an extrapleural pneumothorax was sterilized by the use of "azo-T." Subsequent infection by *Cl. welchii* was successfully treated by azo-T lavage and sulphathiazole instillations.

## CASE HISTORY

A woman aged 35 had been treated for bilateral pulmonary tuberculosis since June, 1939, by extrapleural pneumothorax on the right and intrapleural pneumothorax on the left, the latter being abandoned in Feb., 1942. The right extrapleural pneumothorax was satisfactory until Oct., 1941, when fluid first appeared. In Dec., 1941, the fluid was thin, straw-coloured, and lymphocytic, and contained scanty tubercle bacilli. In Nov., 1942, the character of the fluid had changed; it was then muco-purulent, polymorphic, and there were numerous tubercle bacilli.

Out-patient treatment by aspiration and injection of azochloramide and sodium-tetradecyl sulphate on the lines recommended by Petroff (*Amer. Rev. Tuberc.*, 1941, 44, 738) was instituted on Jan. 19, 1943. Aspirations were at first carried out on alternate days and later twice weekly. The fluid gradually became thinner, and the number of tubercle bacilli decreased until on Feb. 22 no bacilli were present. The fluid remained thin for the next three weeks, but pus cells were persistent. On March 16 the presence of fungal hyphae was noted, and culture of the fluid gave a moderate growth of *Penicillium glaucum*. This persisted in the next two specimens. On March 22 the patient complained of pain in the right side of the chest, and her temperature was 100° F. Her general condition was quite good, but in view of her symptoms she was admitted to hospital. Aspiration was performed on the same day, and next day the bacteriologist reported the presence of *Cl. welchii* in large numbers. *Cl. welchii* serum was administered at once, 40,000 units being given intravenously and 60,000 units intramuscularly. Sulphapyridine was given by mouth, but was replaced by sulphathiazole on March 25, owing to extreme nausea. A further aspiration was performed on March 24, and the bacillus was still present in large numbers.

On March 25, following consultation with Mr. Fatti, treatment by injection of sodium sulphathiazole into the extrapleural cavity was started. The exudate was first removed as completely as possible and lavage of the cavity with azo-T solution performed. Sodium sulphathiazole 8 g., dissolved in 100 c.cm. of normal saline, was then injected. The process was repeated on March 29 and 31. The fluid on both these occasions was negative for *Cl. welchii* and for tubercle bacilli. On March 29 the sulphathiazole content of the clear fluid obtained after autoclaving was 10 mg. per 100 ml., and on March 31, 17 mg. per 100 ml.

The patient's general condition remained surprisingly good and, apart from the extreme nausea caused by the oral chemotherapy, she had no complaints. Her temperature became normal on March 26, and remained so for the rest of her stay in hospital. The white cell count was not affected by the infection or the treatment, the total counts remaining between 7,600 and 8,200 per c.mm., and the differential counts being within normal limits. Fluid gradually reaccumulated in the extrapleural space, and aspiration was again performed on May 4, when the resulting thin, slightly blood-stained, straw-coloured fluid contained only degenerate polymorphs, but no organisms.

The patient was discharged from hospital on May 8, 1943, and has since attended for two further aspirations—in June and July. On both occasions the fluid was thin and sterile.

My acknowledgments are due to Dr. J. N. Deacon, Medical Director, Redhill County Hospital, for permission to publish this paper, and to Dr. A. S. Hall and Mr. L. Fatti for advice on treatment.

MARY G. TATE, M.D.,  
Assistant Medical Officer,  
Redhill County Hospital, Edware.

## Reviews

### RECONDITIONING BY PHYSIOTHERAPY

*Rehabilitation, Re-education and Remedial Exercises.* By Olive F. Guthrie Smith, M.B.E., C.S.M.M.G. With foreword by Lord Horder. (Pp. 412; illustrated. 25s.) London: Baillière, Tindall and Cox, 1943.

The scope of this book is aptly summed up in Lord Horder's foreword. "Reconditioning and rehabilitation," he says, "are in the air; with many folk who pay lip-service to these ideas they remain in the air. In Mrs. Guthrie Smith's book we 'get down to brass tacks,' we follow the special techniques that are appropriate for particular cases, and we realize the extent and the intensity of modern developments in physiotherapy."

For many years the author has preached the gospel of rehabilitation through active exercise, and has earned for herself a deservedly wide reputation for her pioneer work in this field. In her introductory chapter she outlines the basic principles of exercise therapy and deals with the psychological aspects of rehabilitation. In this latter connexion one sentence deserves to be quoted: "The whole art of rehabilitation is to put the responsibility of his own salvation on to the patient, while at the same time making it possible for him to accept this responsibility."

After reviewing the physical and physiological principles underlying exercise therapy, the author proceeds to a detailed account of the various types of exercise appropriate to the re-education and redevelopment of injured or diseased muscles. One of the most important principles in any exercise system is that of progression. In the earliest stages of extreme weakness, such as in poliomyelitis, the muscles require positive assistance—the exercise must, in fact, be "weightless." At the other end of the scale the muscles of labouring men must be hardened by making them work against resistances approximating to the stresses of their work. The physiotherapist must be able to pass from one end of this scale to the other by almost imperceptible stages, and the main part of this book is concerned with a detailed account of how this is done. The author is a pioneer in the development of "weightless" or "suspension" exercises for the early cases, and this is the first account in book form of her original work.

In dealing with resistance technique the various uses of pulley-and-weight apparatus and of springs are discussed, though it is perhaps not sufficiently stressed that these resistance methods have their dangers as well as their advantages. In certain conditions—e.g., in knee-joint injuries—it is of crucial importance to use the correct amount of resistance at all stages, and we hope that in a future edition the author will have something to say on these important matters of dosage and timing in relation to resistance technique. Supplementary chapters, dealing with recovery after fractures, rehabilitation of chest and maternity cases, recreational therapy, electrotherapy, joint manipulation, and plastic operations, are contributed by experts in these particular fields.

This book is well written, well illustrated, and original and stimulating in its outlook. It deserves to be read not only by the physiotherapists to whom it is primarily addressed, but by every surgeon and physician who would wish his direction of the physiotherapist to be intelligent and progressive.

### CONSPECTUS OF PROGRESS IN MEDICINE

*The 1943 Year Book of General Medicine.* Edited by George F. Dick, M.D., J. Burns Amberson, jun., M.D., George R. Minot, M.D., William B. Castle, M.D., William D. Stroud, M.D., and George B. Eusterman, M.D. (Pp. 754. \$3.00.) Chicago: The Year Book Publishers.

The *Year Book of General Medicine* can be relied upon to give a comprehensive view of its swiftly changing panorama. The current volume is no exception to the rule. It is not surprising that a good deal of attention is paid to problems connected with blood transfusion—hence the discussion of the Rh factor, the dosage of either albumin or plasma after a severe injury or burn, and the causes of severe haemolytic reactions. Epidemiology is represented by a thoughtful paper on influenza by C. H. Andrewes, another on malaria as a world menace, and another on epidemic catarrhal jaundice as typically

a military disease which shows regional variations. It is surprising to learn that 2,500 cases occurred during the short battle of Crete. Deficiency in a particular ingredient of the vitamin B complex, which has been labelled "N," is believed by R. M. Calder to aggravate damage to the liver cells. Ankylosing spondylitis is described as a complication of brucellosis. Kidney diseases come in for consideration, particularly in relation to hypertension, and it is interesting to note that, after several swings of the pendulum, lipoid nephrosis is no longer regarded as a separate entity, but merely as a stage in nephritis through which some cases pass. The derided doubters can now recover their self-esteem.

Wartime conditions add to the clinical importance of acute pulmonary oedema. Luisada argues that the physician should have at hand morphine, atropine, sodium phenobarbital, and papaverine hydrochloride. The first three are best when toxic gases, drowning, or skull injuries are the cause of the attack, while in cardiovascular conditions the first two and the last one are to be preferred. Newer concepts in the diagnosis of congenital heart diseases based on clinical and angiocardiac x-ray studies are fully discussed. We would suggest, however, that a classification based on the embryology (and therefore on the evolution) of the mammalian heart would make more intelligible what many otherwise find a mere collection of bizarre distortions. Industrial medicine has received a recruit in the awkwardly named condition of bagassosis. Bagasse is the broken sugar-cane after the sugar has been extracted and is used in the preparation of board. Although this contains 5.7% silica the symptoms differ in several respects from any known form of silicosis, as shown by Castleden and Hamilton-Paterson in our columns (*B.M.J.*, 1942, 2, 478). These are but a few of the many interesting subjects discussed in the *Year Book* for 1943.

### DR. PARKES WEBER'S WRITINGS

*F. Parkes Weber's Collected Writings.* In Celebration of his 80th Birthday and 50th Anniversary as Visiting Physician to the German Hospital, London. May 8, 1943. Edited by the Medical Staff.

The combination of enthusiasm for clinical research and a profound knowledge of medical literature has given Dr. Parkes Weber a unique position in the profession. It was a happy thought, therefore, for his colleagues at the German Hospital to celebrate the 50th anniversary of his election to their staff and his 80th birthday by planning a *Festschrift*. Wartime restrictions have prevented this from taking the form of printing even a selection of his more than a thousand papers. The reported speeches delivered on that occasion were characterized by sincere admiration rather than by eloquence, and, apart from the bibliography, the principal value of this book is the excellent synopsis of his principal contributions compiled by Dr. K. Blum. Dr. Parkes Weber has collected rare diseases as some have collected rare butterflies, but to imagine that it is merely rarity value which appeals to him would be to misinterpret the whole purport of his work. He has used rarities to help towards the explanation of problems of general interest, as the late Sir Archibald Garrod did in his *Inborn Errors of Metabolism*; though he has cast his net more widely. Thus there are pioneer observations on polycythaemia, erythrocytosis, telangiectases, panniculitis, the "pink disease," and the condition now known as Cushing's syndrome. In some instances he has approached generalizations which cannot yet be fully formulated in the present state of our knowledge. This applies particularly to his work on endocrine tumours and abiotrophies. When the time is ripe for such a synthesis it will be found that much of the material has been provided by Parkes Weber. Nor has medicine exhausted his interests, which include numismatics and archaeology.

It is a striking record of what may be accomplished by a man whose ability is accompanied by perennially youthful joy in research and an insatiable thirst for knowledge. We believe that this must have provided him with a happy life for he radiates generous helpfulness to others. He has received many honours, including the Moxon Gold Medal from the Royal College of Physicians, and, having become the Nestor of medicine, is secure in the affectionate admiration of his colleagues.

## INJURIES OF SKULL, BRAIN, AND CORD

*Injuries of the Skull, Brain and Spinal Cord.* Neuro-Psychiatric, Surgical and Medico-Legal Aspects. Edited by Samuel Brock. Second edition. (Pp. 616; illustrated. \$7.00 or 35s. 6d.) Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1943.

Though many of the chapters in this second edition have been modified slightly in the process of revision there are only two outstanding additions—references to the use of sulphonamide drugs in the treatment of wounds and of meningitis, and an instructive account of electro-encephalography after head injury. As only three and a half years have elapsed since the first edition appeared, the small amount of alteration of the work as a whole is scarcely to be wondered at, more especially as the authors are experts, who would therefore have contributed material which was fully up to date in the original edition. It remains a book which will prove most useful to neurologists, surgeons, and psychiatrists who take a special interest in cerebral trauma, for they not only will find much that is of value in the text, but will also be greatly assisted by the numerous but carefully chosen references to the literature. It is not intended as a textbook for undergraduate students, nor will it be fully appreciated save by those who frequently encounter the problems with which it deals.

The chapter on the electro-encephalographic changes which occur in cerebral injury is a helpful guide to anyone who wishes to gain an impression of the methods employed and of the pitfalls that must be avoided in the interpretation of the tracings. A great deal is being learnt about cerebral injury during the war, both in the advanced and in the base areas, and we look forward to seeing these aspects of the subject dealt with as additional matter in the next edition.

## Notes on Books

Fifty years ago the late Prof. EMMETT HOLT first published his *Care and Feeding of Children*. Since 1924 its revision has been in the hands of his son, and now a sixteenth edition has been issued (D. Appleton-Century Company \$2.00). It is intended for the intelligent mother and is largely in the form of question and answer. The book remains, in its latest enlarged revision, a most reliable manual of instruction in the difficult art of successful mothercraft.

The Tuberculosis Association of India has published from 20, Talkatora Road, New Delhi (price 12 annas) a *Directory of Tuberculosis Institutions in British India and Indian States* for 1943. This is designed to give ready and reliable information about the facilities for the treatment of persons suffering from tuberculosis in dispensaries, sanatoria, and other institutions. The first part occupies 70 pages and the second part 20 pages, followed by an index of places listed in British India and in Indian States.

A Supplement to the 22nd edition of Vol. I of the *Extra Pharmacopoeia* (Martindale) has been published for the Council of the Pharmaceutical Society of Great Britain by the Pharmaceutical Press, 17, Bloomsbury Square, W.C.1, price 2s. (plus 2d. postage). It is a pamphlet of 48 pages, recording many changes that have been made, chiefly on account of war conditions, in the *British Pharmacopoeia* and the *British Pharmaceutical Codex*. For the convenience of prescribers and suppliers tables are included taking note of the principal changes made by the publication of a *National War Formulary* and of changes made in the *United States Pharmacopoeia* and the new *U.S. National Formulary*. The pamphlet ends with a summary of recent Statutory Orders affecting supplies of drugs, etc., some newer proprietary names, and corrigenda for Vol. I of the *Extra Pharmacopoeia*.

The second edition of *Revelation of Childbirth*, by Dr. GRANTLY DICK READ (Heinemann; 21s.), is certain to be widely read both by doctors interested in obstetrics and by members of the general public. The theme is babes without fears, and the author presents a strong case to show that fear is the root of much evil in obstetrics. This is by no means a new concept, but nevertheless Dr. Read deserves full credit for the publicity he has given it by word and deed. One wonders whether the cause he sponsors—and what nobler one could be imagined than the allaying of the fears and the pains of childbirth?—is aided as much as it could be by this edition. Constant repetition wearies even the most sympathetic reader and is apt to irritate the critical one. A much-condensed volume would present the case more clearly and forcibly. If such a volume were written it would with benefit omit most of the frequent references to the opposition of the "orthodox profession" to Dr. Read's ideas. These references may make entertaining read-

ing to a "Citadel-minded" public, which will also doubtless enjoy the jibes at obstetrical specialists and anaesthetists, but they achieve no positive results. Medical readers will wonder where all this opposition has been found, and may perhaps be forgiven for wondering if Dr. Read has not been unduly suspicious of even his friends.

E. and S. Livingstone of Edinburgh have published a fourth edition, revised and enlarged, of *Diseases of the Eye*, which forms one of the Catechism Series (price 1s. 6d., plus 3d. postage). The strength of this booklet is its concise orthodoxy. The new edition shows evidence of reluctant departure from orthodoxy on several points. Revision of the text for a further edition might with advantage be entrusted to an impenitent iconoclast.

## Preparations and Appliances

### A HEAD HARNESS FOR ENDOTRACHEAL ANAESTHESIA

Dr. A. OWEN-FLOOD (London, N.8) writes:

Most anaesthetists have experienced the annoying episode of the endotracheal tube slipping out of place when applied through either the nasal or oral route. It occurs mostly when the patient is placed in the Trendelenburg position during an abdominal operation. There is an avalanche of pillows, tube, and connecting gear, falling with a loud clatter to the floor. The patient promptly "comes out" and starts to strain his intestines through the incision. The surgeon gives the anaesthetist a glance aptly described in Ireland as "a look like a summons," and the latter's frantic efforts to find and replace another sterilized tube produces an atmosphere described in diplomatic parlance as "tense."

The little device here illustrated avoids all this. Its construction is simple and the cost of materials negligible. Nearly every practitioner has in his possession a laryngologist's reflecting mirror clamped to a forehead plate by a small metal post

surmounted by a knob. Detach the mirror and clamp and file off this knob, leaving as much of the post as possible. Obtain from any hardware stores a good high-grade tempered steel clip (Ferry's is a suitable type) of sufficient size to retain the connecting-tube holder on the Boyle's apparatus or other source of anaesthetic. The clip is placed on to the post of the forehead plate. It is not necessary to use a rimer as the hole in its base fits snugly on the post. Place a small washer over the latter and fix this firmly to it with a blob of solder. Take care that the solder does not fall on the clip. This must not be fixed to the washer, but should be allowed to rotate freely in its horizontal axis around the post.

When in use the plate is attached to the patient's head by its original strap, and the connecting joint to the anaesthetic apparatus is fitted in the clip. This is in turn connected with the tracheal tube protruding from the nose or mouth by any type of connector which ensures a clear airway.

Supplies of "tabloid" brand "iodicin" (capsules), gr. 3, in tins of 50 and bottles of 250, are again available. Wartime conditions have necessitated a change in the shape of the capsules, but the therapeutic activity is unaltered. "Iodicin" is an organic iodine preparation for oral administration in place of the inorganic iodides. Descriptive literature can be had from Burroughs Wellcome and Co., 12, Red Lion Square, W.C.1.

## BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 11 1944

## THE HEALTH OF NEW YORK

The health department of New York City realizes that the health records of any year lose much of their interest if they are not published promptly. On each New Year's Day, therefore, Dr. Ernest L. Stebbins, the health commissioner, presents to the Mayor and issues to the Press a summary report for the year that ended the night before. War apparently is no obstacle. The report for 1943 is quite a substantial document running to thirteen closely typed foolscap pages, and comparing the more important of the year's statistics with those which have gone before. There appears to be no valid reason why our own public health units should not be able to do the same.

The population of New York is 7,625,000. It is therefore the most populous urban unit for which comprehensive health data are available, and big enough to give its annual figures meaning without the cruder statistical fallacies. For many years the improvement in the mortality from most causes and in the incidence of some diseases has been great and continuous. For instance, the infant mortality rate has fallen from 120 per 1,000 live births in 1900-9 to 30.2 in 1943; and the neonatal rate from 36.2 in 1910-19 to 21.5, a decline of 40% even in this most refractory part of the child mortality. Rates such as these are not exceptional in the U.S.A., or indeed in some British Dominions and foreign countries; but no large city in the United Kingdom can approach them. Both rates were, however, a little higher than in 1942, mainly because of diarrhoea, pneumonia, and accidents. The maternal mortality rate, also, which remained long at a high level in New York, has dropped from 6.0 per 1,000 live births in 1931 to 2.1, and is now lower than the 1942 rate for London. As elsewhere, the greatest decline has occurred since the introduction of sulphonamides in the middle thirties, and it is therefore probably most evident in the septic causes.

There is little interruption in the well-known campaign to *extinguish diphtheria* in New York. In this huge population 281 cases were notified in 1943—the lowest number on record—compared with an annual average of 14,282 in 1910-19 among a much smaller population. Six large districts of New York have recorded no deaths for periods varying from 5 to 8 years. The health commissioner expresses concern that the deaths in the whole city rose from 7 in 1942 to 16 in 1943. In 1942 London County, with fewer than 4 million people, had 1,813 cases and 51 deaths. This is a measure of the leeway we have to make up in immunization. But perhaps even more striking is the falling mortality from measles and whooping-cough, diseases which have not materially changed in their periodical incidence and which have been uninfluenced by any systematic application of specific prophylaxis. The mortality from measles per 100,000 children under 5 years

of age has fallen from 27 in 1930-3 to 2.5 in 1940-3; whooping-cough from 29 to 10.3. As elsewhere, measles, though more common—or perhaps more commonly recognized—is now by far the less fatal of these two diseases.

New York, however, has not entirely escaped the health hazards of war. Meningococcal meningitis had been at a low ebb, with 48 cases and 17 deaths in 1940, when it was ravaging this country. Since then it has increased continuously, and more rapidly during the last two years, when 411 cases with 84 deaths and 1,412 cases with 233 deaths were respectively recorded. The case-mortality rate was 16.5% in 1943 compared with 50% only a few years ago—another instance of the beneficent effect of sulphonamides. The decline of tuberculosis also has been interrupted. The rate for 1942 had been a low record at 46.2 per 100,000 from all forms of the disease; in 1943 it was 47.9, both the respiratory and other forms contributing to the rise. Apparently the exceptional increase in meningeal tuberculosis which was a feature of the British statistics of 1940 has not been observed in New York. The health commissioner attributes the retrogression to the fact that people with previously healed lesions have succumbed to the overwork of wartime. In comparing the New York tuberculosis rates with those of British towns an increment of about 15% should be allowed for residents dying elsewhere without transfer of the death record. Since 1941 venereal diseases have become more prevalent. In the first eleven months of 1943, 23,594 cases of syphilis of all types were recorded. The number of early infectious cases reported in the first ten months of the year was 3,433, representing an excess of 39% over the figure for the corresponding period of 1941; and the 15-24 age group was especially affected. The anti-venereal-disease campaign has been intensified. The health commissioner also expresses concern about an increase in deaths from pneumonia, the rate per 100,000 having risen from 39 in 1942 to 50.5 in 1943. There was an excess in almost every month in comparison with the previous year. He regards it as disturbing in view of the availability of specific means of treatment. The really great increases in certified causes of death, however, are revealed, as in most civilized countries, among the chronic diseases of later life. The rate of diabetes has risen from 25.7 in 1930 to 42.7 in 1943; for cancer (unstandardized) from 117 to 172.7; and from that heterogeneous group which includes diseases of the heart, arteries, and kidneys, and apoplexy, from 381.5 to 533.1. That these increases are due mainly to more accurate certification or classification and to changes of medical fashion, and only to a slight extent to change in the real causes of death, may be concluded from the fact that the crude general death rate has remained virtually stationary throughout these years (10.9 per 1,000 in 1943), although the population affected has been growing older and therefore more likely to swell these categories in the lists of death.

The prompt issue of New York's health statistics each year will make it possible to follow closely the course of events in wartime and perhaps to learn new lessons. Will diphtheria remain at a low level if drafts of medical men and nurses to the fighting Forces make it impossible to keep up the level of immunity of the children? Will tuberculosis increase from wartime strain and, even in America,

from some degree of food shortage? Or will fuller employment and higher wages counteract these latter influences? Will influenza, which touched New York in December as it did here, return with renewed force this year or next and smudge the whole statistical picture? At least we shall not be kept long waiting to know about it. In the meantime it must be recognized that much of the success achieved in New York is due to the vigour and persistence with which both the health department and voluntary organizations have applied themselves to the education of the people in health matters. We need not wait to learn this lesson.

## A TOXIC FACTOR IN TRAUMA

Traumatic shock is the name given to a clinical syndrome fairly common in centres of industry even in times of peace. In war, however, it provides problems which are urgent everywhere. At the end of the last world conflict it was commonly believed that the shock which appeared some time after the injury was the result of some toxic absorption from the damaged tissues, and all that was left unsolved was the isolation of the toxin. Since then this view has lost much of its appeal, and attention has been paid to adrenal exhaustion, loss of fluid, and reduction in the activity of the sympathetic nervous system. Evidence exists which favours every one of these as an important factor in the pathogenesis of shock, and much of the modern treatment of shocked patients derives from the conception that the maintenance of an efficient circulatory volume is all-important. While the need for transfusion is granted, there are records of too many cases in which the loss of fluid, even when calculated generously, is insufficient to explain the clinical phenomena. Recent work by H. N. Green<sup>1</sup> suggests a return to the hypothesis of toxæmia. Using rats with experimentally produced hind-limb ischaemia, he found that survival of the animal depended on amputation of the injured limb as soon as possible after the removal of the clamping apparatus. This fits in admirably with the point emphasized by Grant and Reeve<sup>2</sup> that in cases of traumatic shock surgical treatment must be carried out as soon as possible after the circulation has been adequately restored. Green further demonstrated that restoration of fluid volume in the rats had by itself little effect in diminishing the mortality rate. Another fact of importance which was elicited was that the animal could survive a very long asphyxia provided that it was induced for short periods separated by intervals. As Green points out, this suggests that some toxic factor produced at the site of injury is in some manner got rid of, provided too large a dose is not suddenly thrown into the circulation.

A comprehensive account is given by Bielschowsky and Green<sup>3</sup> of the methods adopted in isolating and determining the nature of this "myotoxin," and it is concluded that it is adenosine phosphate. Of more immediate importance to the clinician is the effect of this toxic factor on the animal. Injection by any of the parenteral routes causes a rapid fall of blood pressure, progressive weakness, and

rapid shallow breathing, followed by slow irregular respirations which precede death. Haemoconcentration is an important feature which is almost certainly associated with the great amount of fluid in the damaged tissues and elsewhere, the marked congestion of liver and great veins, and the haemorrhages into lungs and digestive tract. It is interesting to note that with intraperitoneal administration the lethal dose of the toxic factor is smaller than for other routes—a fact which may be connected with the very large volume of intraperitoneal exudate that is produced. The effect on the kidneys is especially worthy of note. Anuria was always observed even when large amounts of fluid were injected simultaneously, suggesting that the toxic factor had some direct action on the renal cells; and the hypothesis seems worth considering that the permeability of the tubular epithelium is greatly increased, allowing the complete reabsorption of the glomerular filtrate. This view is favoured by the author's impression of pathological changes in the lining cells of both the first and second convolutions. In this context the observation that injection of myohaemoglobin enhances the effect of the toxic factor brings to mind the clinical conditions in which haemoglobinuria is said to play a part in the pathogenesis of anuria. Green displays a natural caution in drawing analogies with the syndrome of shock as seen in man, but it appears justifiable to conclude that the state brought about by the toxic factor is worthy of the designation of shock and that it presents features which are very similar indeed to those presented by the crush syndrome. In any event a new field has been opened to pathologist and pharmacologist, while the clinician's heart is uplifted in the hope that more light is to be thrown on the age-old problem of shock and more help given for its prevention and treatment.

## THE HEALTH OF BELFAST

The report for 1942 of the medical officer of health, Dr. C. S. Thomson, though curtailed, gives a comprehensive review of the health of the city of Belfast. The general death rate was only 11.2 per 1,000; during the preceding 20 years the mortality had ranged from 12.9 to 15.6. The birth rate, 21.7 per 1,000, was the largest for eight years. The infant mortality during 1942 was high—92 per 1,000 births. There has been only a very slight improvement in the infant death rate during the past two decades, and this has been masked to some extent by wide annual fluctuations. The range during this period has varied from 78 in 1930 to the appalling figure of 122 in 1940. As a result of such a high infant mortality there were, in 1942, more deaths recorded in the first year of life than in the forty years from age 5 to 45. The causes of infant mortality are not given in the report, but it is evident that an important factor is diarrhoea and enteritis; during the preceding 20 years the highest and lowest mortality from this cause corresponded with the highest and lowest infant mortality. Deaths from diarrhoea and enteritis under 2 years of age numbered 166 in 1942. In contrast to the high infant mortality the rates for maternal mortality and stillbirths were relatively low, being 3.2 and 38 per 1,000 respectively. Mortality from tuberculosis in 1942 fell to the pre-war level following the rise in 1940–1 which interrupted the almost continuous decline of the interwar period. The deaths for 1939–42 were 365, 412, 426, 369 for pulmonary tuberculosis, and 71, 94, 98, 79 for other forms. During the

<sup>1</sup> *Lancet*, 1943, 2, 147.

<sup>2</sup> *British Medical Journal*, 1941, 2, 293, 329, 332.

<sup>3</sup> *Lancet*, 1943, 2, 153.

29 years 1914-42 mortality from respiratory tuberculosis has been more than halved, while mortality from non-pulmonary forms has been reduced by three-quarters. The results of the campaigns against diphtheria and venereal disease are reviewed in the report. For diphtheria the immunization scheme continues to make steady progress, and over 44,590 children have received a course of treatment. The number of children under 15 immunized was 9,506 in 1942 and was 2,150 fewer than in the preceding year. The proportion of the child population under 15 immunized is only about one-third, and less than one-quarter of the pre-school children have had treatment. In 1942 369 cases of diphtheria with 15 deaths were reported, compared with an average for the preceding ten years of 828 and 40. The results obtained under Regulation 33B from its commencement in the spring of 1943 to the end of July, 1943, are stated to be most disappointing, and no headway whatever has been made in the control of venereal disease, which has increased very much lately. Dr. Thomson considers 33B a failure and advocates compulsory notification, and he suggests the immediate adoption of the New York regulations which became law in January, 1918.

### PULMONARY ABSCESS

Few parts of the body provide so many pitfalls for the uninitiated surgeon as the thorax, and the treatment of a lung abscess can be one of the most difficult problems in thoracic surgery. A recent exposition by Brock<sup>1,2</sup> of the surgical approach to abscesses in the upper lobes is therefore particularly welcome, and stands out from the vast and diffuse literature of this subject because of the characteristic thoroughness and clarity of its presentation. Brock first describes the anatomy of the bronchi of the upper lobes, showing that the successful drainage of a lung abscess can rarely be achieved without a knowledge of this subject. Comparison of other recent accounts of bronchial anatomy (Foster-Carter<sup>3,4</sup>) with this one shows that there is now substantial agreement about the distribution of the upper-lobe bronchi, including those of the axillary regions, the sole exception being the shape of the broncho-pulmonary segments forming the "lingula" of the left upper lobe. Here Brock considers that the division between the two segments is horizontal rather than vertical. He then emphasizes the importance of accurate location of a lung abscess and describes in detail how this can be achieved. Very careful location is essential in order that drainage may be performed with a minimum of damage to the patient at the site of election—where the abscess is nearest to the chest wall. For instance, the commonest site for a right upper-lobe abscess is the sub-apical (posterolateral) segment; it is of the utmost importance for the surgeon to determine whether the abscess is situated in the posterior or the lateral subdivision of this segment, because the surgical approach is completely different in the two cases. Failure to recognize these facts results in what Brock calls the "blunderbuss" method of attacking a lung abscess, with multiple rib resections and extensive damage to the chest wall and healthy lung tissue. An adequate knowledge of the complex bronchial supply of the so-called "axillary" areas is also indispensable when locating and draining abscesses of these regions.

In another investigation Brock<sup>5</sup> has confirmed the pioneer work of Koch and Wieck<sup>6</sup> who showed that the posterior end of the main interlobar fissure on both sides

is at a lower level than is commonly supposed. The apex of the lower lobe is rarely higher than the posterior end of the fifth or sixth rib, and consequently an abscess of this area will require drainage by resection of a rib below this level, commonly the eighth rib. Textbook descriptions, on the other hand, would lead one to expect such an abscess to lie above the sixth rib, because the level of the lower-lobe apex is given incorrectly as the third dorsal transverse process.

The experiments of Quinn and Meyer<sup>7</sup> in 1929 showed that lipiodol introduced into the nose during sleep flowed readily into the lungs, and this has been held to support the theory that lung abscesses are due to the inhalation of infected material. Brock, Hodgkiss, and Jones<sup>8</sup> describe with much more precision the exact areas reached by small quantities of iodized oil introduced into the trachea with the subject in various positions. It is significant that, when the patient lies on his back, the oil flows into the subapical (posterolateral) segment of the right upper lobe and into the apical (dorsal) segments of the lower lobes. When the subject lies on his side the oil gravitates, as would be expected, into some part of the "axillary" region of the dependent upper lobe. These areas are the commonest sites for the occurrence of a lung abscess, and the authors conclude that most pulmonary abscesses are caused by the inhalation of infected material during sleep or anaesthesia. They state also that the lesions of pulmonary tuberculosis commonly affect the same areas, and suggest that these too are the result of bronchial embolism. Without underestimating the value of these experiments, it is still important to preserve an open mind on this subject, remembering that other theories, also supported by experimental evidence, have been advanced. The distribution of the pulmonary artery is very like that of the bronchi, but it has not yet been studied so extensively. The experiments of Cutler<sup>9</sup> on the production of lung abscess and of Chien-Liang Hsu<sup>10</sup> on the formation of tuberculous lesions, to mention only two examples, suggest that infected vascular emboli may also be a factor in the pathogenesis of pulmonary infections. It is therefore unjustifiable to adopt a dogmatic attitude towards this problem at the present time, but in many cases of lung abscess the evidence appears to favour an aspiration origin.

### EXTENSION AT ROEHAMPTON

An extension of the limb-fitting centre at Queen Mary's (Roehampton) Hospital was opened recently by Dr. Wellington Koo, the Chinese Ambassador in London. The extension includes a spacious demonstration theatre, with annexes, and is equipped with cinematograph apparatus, for lectures and classes on the science of limb-fitting. This follows upon a resolve of the governors, largely at the instigation of one of them, Kathleen, Viscountess Falmouth, to bring the facilities at Roehampton to the attention of the representatives of the various Allied Governments now in this country. In this way we may hope that the knowledge and experience gained at Roehampton will become widely available in European countries after the war. A number of new workshops have also been built with a view to dealing with the many limbless cases which are the result not only of war but of injuries in industry and transport. In a graceful little speech in the new demonstration theatre Dr. Wellington Koo said that Roehampton furnished a fascinating story of successful endeavour in practically a new field of service to humanity. He handed the key of the extension

(made in duralumin, the same metal as that in which the artificial limbs are constructed) to Sir Walter Womersley, Minister of Pensions, who said that numbers of medical men from the Allied nations had already attended at Roehampton, and in the factories some Polish nationals were actually being trained in limb construction with a view to starting a factory under Government auspices at Warsaw on their return. He added that in the extension post-graduate courses would be provided for medical men from this country as well as from abroad, and training would be given to medical auxiliaries and to women who wished to learn the technique of nursing amputation cases. It was hoped also that Roehampton would be the scene of surgical conventions. A film of the work was shown, and a demonstration was given by patients so adept that one realized with difficulty that they were wearing an artificial limb at all.

### SMALLPOX: A WARNING

On Feb. 6 a military patient from the Middle East was admitted to the Mount Vernon Emergency Hospital, near Rickmansworth. He had been vaccinated successfully in infancy and again two years ago. After a few days he had what was regarded by competent medical officers as measles and chicken-pox, and the true nature of the condition was not found out until an unvaccinated nurse who had been in attendance on him, and an unvaccinated visitor to the ward in which he was, developed confluent haemorrhagic smallpox. Both these patients died. Subsequently, four vaccinated nurses developed modified smallpox and had much the same manifestations as the primary case; all are mild cases of the disease. A 52-year-old patient, vaccinated as an infant, died from a severe attack. He was in a ward next to that in which the primary case occurred, the staff being common to the two. All the cases were confined to a small division of the hospital, and, so far as is practicable, all recent contacts have been traced and vaccination or re-vaccination offered. It has, however, not been possible to trace a large number of visitors to the hospital, and practitioners are asked to bear this in mind when called in to see doubtful cases. The strain of virus is intensely virulent, but is obviously so susceptible to vaccination as to obscure the classical picture and make diagnosis difficult. The possibility of diffusion cannot be disregarded, and practitioners and medical officers of health are reminded of the assistance in diagnosis which is available from the medical staff of the Ministry of Health, both regional and central, and from the London County Council.

### THERAPEUTIC ABORTION IN SWITZERLAND

English gynaecologists are familiar with the problem of how far therapeutic abortion is permitted by law. Mr. Aleck Bourne's case<sup>1</sup> brought a little light in Mr. Justice Macnaghten's instruction to the jury, where his lordship stated that pregnancy may lawfully be terminated to save the mother's life, and that "life" includes not only survival but also a reasonable prospect of health. Medical speakers have from time to time demanded that Parliament should give some protection to the qualified medical man who terminates pregnancy in good faith for the protection of his patient's health. The Swiss legislature actually passed a law of this kind in 1941,<sup>2</sup> but it does not seem to have entirely simplified the position; in fact, Dr. Alfred Labhardt has explained<sup>3</sup> at some length the new medico-legal problems which it raises. It provides that a qualified medical practitioner may lawfully intervene if a number of conditions are satisfied. The doctor must be in actual practice, and the patient must consent in writing

(the husband's consent is not required). The reason for the operation must be medical: the immunity does not extend to social, legal, or eugenic grounds. Intervention is justifiable only if the disorder for which it is undertaken directly menaces life or involves great danger of severe and lasting injury to health, and if the danger cannot be averted in any other way. The necessity must be confirmed by a second medical practitioner, who must be a specialist in the disease for which the operation is considered. Dr. Labhardt observes that this is the first time the standing of a specialist has been recognized in a Swiss statute, and says the profession had to fight hard to get it inserted. The specialist is named by a specially appointed authority of the canton—in Basle the chief medical officer—from a panel submitted by the representative professional body.

In towns where several specialists are available the patient's doctor may choose his second opinion; if one specialist does not agree with him he may call in another, but he must disclose the opinion of the first. Differences of opinion may be resolved in consultation with the head of the specialty. The State has no further part in the operation, and professional secrecy is fully maintained. The second opinion must be given in writing after an exhaustive study of the history and personal examination, and must go fully into the prognosis, the need for the operation, and the possibility of using other methods. The specialist must certify in the exact words of the statute the existence of a danger to life that cannot otherwise be averted, or of a great danger of severe and lasting injury to health. The specialist, the patient's doctor, and the operator should, Dr. Labhardt recommends, each keep a copy for at least five years, together with a copy of the patient's form of consent. The second opinion may be dispensed with in an emergency—e.g., in rural practice or on the operating table—but the circumstances must be reported within 24 hours to the health department of the canton. A doctor who intervenes for reasons, however weighty, that are not strictly therapeutic is not exempt from punishment, but the court may take them into account in deciding the penalty. (In England, where no minimum penalty is laid down except for murder, the court could do this without a statutory provision.) Dr. Labhardt thinks, nevertheless, that non-medical grounds should be dealt with in the specialist's written opinion. He also feels strongly that a doctor called in to terminate pregnancy after a formal opinion has been given in favour of intervention should thoroughly investigate the case himself and not rely blindly on the opinion. It is therefore desirable that the chief surgeon of the clinic or department where the operation would be performed should take part in the consultation at which the intervention is discussed, so that he will not have to refuse at the last moment.

Most Swiss gynaecologists probably agree with Dr. Labhardt that the new law substantially improves their position. It enacts in precise statutory form very much the same principles as Mr. Justice Macnaghten enunciated in the Bourne case. The policy in this country, on the contrary, has been deliberately to avoid precision and to trust the integrity of the medical profession to observe loyally a largely unwritten law. The Bourne case so far satisfied the advocates of precision that they have not since made a concerted demand for legislation. Our professional honour is perhaps better served by Mr. Justice Macnaghten's sympathetic statement on what we may do than it would be by a cold statutory formulation of what we may not.

The Council of the B.M.A. at its meeting on March 3 appointed Dr. Charles Hill to the vacant post of Secretary of the Association.

## MR. CHURCHILL WITH THE PHYSICIANS

The Prime Minister was the principal guest at a luncheon party given on March 2 by the Royal College of Physicians of London. There were two speeches, one by the President (Lord Moran), who proposed the health of the guests, and Mr. Churchill, who in his reply gave the toast of "The College."

## Science, Action, and Character

Lord MORAN, in the course of his speech, said:

"I was under the impression that my wanderings were a new chapter in the long history of the College, but the annals are full of the travels of my predecessors—to the Court of France, to the Low Countries, and to Spain. . . . It is perhaps inevitable, having spent so many hours in the ante-chamber of Councils of War, that I have come to compare the profession of medicine and the profession of arms. Progress in both professions has always come by jumps punctuated by long periods of stagnation. . . . In comparing the professions one asks whether the same qualities are needed in both. For some years now I have come much into contact with soldiers, and as a doctor I see no reason to believe that the scientific mind is more common in my calling than in the Army. At any rate, that is true if I am speaking of practising physicians and surgeons. I hasten to add that qualification, for there are half a dozen creative minds in the profession of medicine who have no counterpart in the Army—Sherrington, Adrian, Dale, Gowland Hopkins, Thomas Lewis, Almoth Wright, all Fellows of our College. There is, too, no machinery in that Service like the Medical Research Council for the discovery of men with a creative instinct at the outset of their careers. Such men would carry out research into tactics and weapons—for example, the limitations of the anti-tank rifle would have been laid down before it was used in battle. But I am not sure if the conditions of the two professions are strictly comparable. I doubt whether the direction of armies in war calls for the creative instinct in the same measure as does research into the origin of disease. . . . There is one other qualification I must make. I am bound to ask if the conditions of the soldier's life and training are friendly to the development of the scientific mind. Discipline does not foster independence of thought, while life in a regimental mess hardly encourages those habits of reflection that are only bred in solitude. Further, there is the fetish, not confined to soldiers, that the mind works best when the body is exhausted by exercise.

"There is one quality which both callings need. The first and the last essential of an efficient soldier is character; without it he will not long endure the perils of modern war. Even in the last war the durability of a general—his survival value—seemed to depend more on character than on capacity. We may doubt the pre-eminence of Foch, Haig, Jellicoe, and Trenchard in their art, but as men they came from the old mould of their race. They wore well, they were built for great occasions. In the fundamental clash between great nations when their existence is at stake the issue is determined by moral and not by intellectual factors. The part that character plays in medical diagnosis is not always appreciated. It is the quality which allows judgment to be exercised irrespective of worldly considerations which may snare the feet of the lighter breed of doctor. I end my comparison with a paradox. The successful doctor sees a stranger almost every hour of the day, and he must not only find out what is wrong with him but must learn to gauge his temperament and his outlook, what he wants to know and whether he is going to do what you tell him, and so the physician, after 30 or 40 years, becomes an expert judge of men, but he cannot use it in devolving his work. He must exercise his lonely art as an individual. Now the soldier who has not the art of selecting his subordinates is lost, but it is the paradox of the situation that, unlike the physician, he gets few opportunities in peacetime of practising this art. Even individual criticism is discouraged in the mess."

Lord Moran ended with a glowing tribute to Mr. Churchill, measuring his contribution to victory by attempting to define more precisely than had been done the exact nature of his task. That task as he saw it was the moral preparation of the youth of England for ordeal by battle. The art of command was the

art of impressing the imagination. When the surge and thunder of the Prime Minister's vast vocabulary were heard no more history would recount how he spread abroad a sense of purpose and direction which gave men hope when there was really none. "More than once I have been with him when news of shattering reverses was brought to him, and in my heart I have come to think of him as invincible."

## The Government's Health Policy

The PRIME MINISTER, who was received with loud cheers, began by thanking his cherished friend, Lord Moran, for all the kind expressions he had used about him. After speaking of some remarkable and inspiring recent advances in medicine, he said that the discoveries of healing science must be the inheritance of all. Disease must be attacked, whether it occurred in the poorest or the richest man or woman, simply on the ground that it was the enemy. The Government had adopted the policy outlined in the words of Lord Beaconsfield on health and the laws of health, and that was the course upon which it had embarked.

"Our policy," said Mr. Churchill, "is to create a national health service in order to ensure that everybody in the country, irrespective of means, age, sex, or occupation, shall have equal opportunities to benefit from the best and most up-to-date medical and allied services available. The plan that we have put forward is a very large-scale plan, and in ordinary times of peace would rivet and dominate the attention of the whole country; but even during this war it deserves the close study and thought of all who can spare themselves from other duties for that purpose. We welcome constructive criticism; we claim the loyal and active aid of the whole medical profession. Any health services must rest on two arches: the first, the general practitioner, the rank and file of the profession; the second, the hospital service, depending upon the staffs of the hospitals, sustained and guided by the consultants."

"The fact that many more consultants will be needed in the future than there are now must not result in dilution or in the lowering of the standard of consultant work. There is a new gap to be filled, and in this new effort the Colleges must play their great part. We ask your aid: we invite your counsel. Tackling together these vast problems we may take a forward movement which will be notable and permanent in its effects long after the roar of cannonade has died away. We have to-day announced the names of the Royal Commission on Population. There is no branch of human knowledge in which we can pierce the mysteries of the future so clearly as in the trend of population. Here you have prophecies which rest on certainty; here the searchlight of statistics ranges with accuracy for 30 or 40 years ahead. The destiny of our country, which after all has rendered notable services to mankind in peace and latterly in war, depends upon an ever-flowing fountain of healthy children, born into what we trust will be a broader society and a less distracted world. Science, now so largely perverted to destruction, must raise its glittering shield not only over the children but over the mothers, not only over the family but over the home. In all this field again you must be active. Your services will be given with devotion and your voice will be heard with respect."

"This College must play its part in keeping alive the historic tradition of the medical profession, and must ever foster those high standards of professional behaviour which distinguish a profession from a trade. This is what you have tried to do as an institution for 400 years. I confess myself to be a great admirer of tradition. The longer you can look back the further you can look forward. The wider the span, the longer the continuity, the greater is the sense of duty in individual men and women, each contributing their brief life's work to the preservation and progress of the land in which they live, of the society of which they are members, and the world of which they are the servants."

Infant mortality in Belgium per 1,000 live births was 81.3 in 1939, 93.2 in 1940, 92.3 in 1941, and 96 in 1942 (*Arch. méd. belges*, 1943, 96, 1). The nutritional condition of children under one year in 1941 and the first half of 1942 was still satisfactory. Diseases are not commoner than formerly except for slight traces of rickets, which occur even in breast-fed children. Altogether 62% of children are breast-fed. Usually, after the third month, only 25% are still breast-fed.

## For Prostatic Carcinoma

### STILBOESTROL-BOOTS

Clinical results have confirmed the value of Stilboestrol in the control of prostatic carcinoma.

Kable et al. (*J. Urol.*, 1942, 48, 83) reported prompt relief of pain and urinary symptoms, the clinical improvement being associated with the regression of the malignant lesion both primarily and metastatic.

Dodds and Walker (*Brit. med. J.*, 1943, 2, 436) observed eight cases of carcinoma of the prostate which were rendered completely symptom-free by Stilboestrol treatment.

# ANACARDONE

TRADE MARK

(NIKETHAMIDE B.D.H.)

Anacardone is the standard analeptic (Nikethamide B.P.), characterised by its rapidity of action, wide range of therapeutically effective dosage and freedom from toxic effects.

## INDICATIONS

### In Anaesthesia

Cardiac and respiratory depression.

Control of the depth and duration of basal or intravenous anaesthesia.

### In Poisoning and Shock

Collapse associated with poisoning with barbiturates and other narcotics.

Traumatic, electrical or obstetric shock.

### In Obstetrics

Distress during labour, cardiac failure following post-partum haemorrhage and asphyxia neonatorum.

### In Infective Diseases

Cardiac and respiratory inadequacy in infective diseases such as diphtheria, measles, pneumonia, influenza and typhoid fever.

### PACKINGS. Solution for parenteral administration (Inj. Nikethamid. B.P.)

2 c.c. Ampoules - Boxes of 6, 12, 25 and 100

5 c.c. Ampoules - Boxes of 3 and 12

Solution (25 per cent., with flavouring) for oral use

Bottles of 15 c.c. and 100 c.c.

*Details of dosage and other relevant information will be gladly supplied on request.*

## CO-ORDINATION...

When the success of a plan depends upon its perfect execution there must be strict co-ordination between the individuals involved. No programme of treatment can relieve the *incidence of constipation unless the patient* is willing to co-ordinate his efforts with those of the physician. That is why so many doctors prescribe 'Petrolagar' for their patients . . . Its pleasant taste and gentle consistent action are acceptable to the patient as well as to the physician.

### ACTIVE CONSTITUENTS IN FORMULA :

'Petrolagar' with Phenolphthalein : White Petroleum Oil

25%, v/v, Phenolphthalein 1½ grs. to the fluid ounce.

'Petrolagar' Plain : White Petroleum Oil 25%, v/v.

## Reports of Societies

### THE R.A.F. MEDICAL SERVICES AND THEIR CONTRIBUTION TO THE WAR EFFORT

At a meeting of the Medical Society of London on Feb. 14 Air Marshal Sir HAROLD WHITTINGHAM, Director-General of Medical Services, R.A.F., lectured on the contribution which that service had made to the war, as regards selection of personnel, prevention of disease, treatment of sick and injured, rehabilitation, transport of casualties by air, and the maintenance and improvement of physical and operational efficiency.

#### Selection Tests

He dealt first with the selection tests for pilots and others. A new hearing test, using a pure-tone audiometer with a noise background simulating the noise experienced in aircraft, had been devised with a view to replacing or reinforcing the 20-ft. whisper test. As for visual tests, some maintained that as the pilot flew by instruments at night no night visual standards were necessary. On the other hand, the pilot might be compelled to land on a strange airfield after a long flight over the Continent, or to land even on a familiar airfield when intruder aircraft were about, and he might experience crowding over the target. The possibility of taxiing accidents was doubled at night. Therefore tests and standards for night vision seemed to be necessary. There were also clinical tests for cardiovascular stability in selecting pilots suitable for aerobatics. Those who had a low blood pressure and showed no rise in the diastolic blood pressure in change from the horizontal to the vertical on the tilt table were usually rejected. The Navy was the first Service to adopt mass radiography, but the R.A.F. was the first to use mobile units for this purpose. Since 1941 over 400,000 such examinations had been carried out. Among those examined 2.8 per 1,000 males and 3.6 per 1,000 females were found to have active tuberculosis.

#### Maintenance of Efficiency and Disease Prevention

Sir Harold Whittingham next spoke of the maintenance of flying efficiency. One innovation was the flying personnel medical officer. A number of medical officers had their wings and flew with the men, or piloted aircraft themselves, making observations and linking up with the research team. Some of these officers were sent abroad to the different fronts to study special flying problems from the point of view of human efficiency.

Turning to prevention of disease, he showed a chart illustrating the striking improvement in the health of the R.A.F. The Force was now at the healthiest point in its history in either peace or war. In this respect a 25% improvement was shown in 1941 over 1940, and again in 1942 over 1941, but in 1943 the improvement was only 10%, simply because the position was now so good that the scope for improvement was restricted. A team studied dietetics and assessment of food values. The general instruction was that diet must not be modified in such a way as to increase transport or financial outlay, though now and again some vitamin deficiency was revealed and it was necessary to send special foodstuffs. At Malta during the siege some men suffered from night blindness, which persisted in spite of extra doses of vitamins A and C, but within a week of a surfeit of oranges becoming available night vision went back to normal, suggesting that some factor essential for good night vision is present in oranges. Dental hygienists were now for the first time introduced into the R.A.F.—a quite considerable body of them—and were doing first-class work in scaling and polishing teeth as well as instructing air men and women how to care for their teeth. The breakdown rate from nervous conditions had proved extremely small.

#### Evacuation of Casualties by Air

With regard to the evacuation of casualties by air Sir Harold Whittingham said that the R.A.F. had transported about 28,000 sick and wounded during hostilities in the Mediterranean war zone, including a number from North Africa to the United Kingdom. As was to be expected, Army cases greatly preponderated.

#### Hospital Provision

Hospital provision included specialist centres such as those for plastic surgery, the treatment of burns (specially equipped with brine baths), and orthopaedics. The R.A.F. mobile field hospital usually consisted of 100 beds, expandable to 200 by means of stretchers. The hospital packed up entirely into 28 vehicles, and in the Western zone one was supplied for each 10,000 personnel. In tropical and subtropical zones the provision was one to every 5,000 personnel. He described the flying surgical section—which was in Sicily on the second day of the invasion—and the special scheme for the collection of casualties and sea rescue. To discover the best method of effecting sea rescue of disabled and unconscious men, one medical officer had himself anaesthetized and thrown repeatedly into a swimming bath. The result was an improvement in the design of the "Mae West jacket," but it cost the medical officer four days in hospital afterwards on account of the exposure.

#### Rehabilitation

A first-class system of rehabilitation in the Royal Air Force was started during the Battle of Britain in 1940 and had since been extended and was in practice on every front. A large number of rehabilitation orderlies were employed to see that the necessary exercises, beginning in the hospital, were carried out. Cases were sent from hospital to rehabilitation centres so designed as to remove any hospital atmosphere for psychological reasons. Each patient was required to be taught to walk properly from the beginning, otherwise he acquired a limp; he was taught to walk up and down steps; and finally to jump 10 feet into a sand pit to simulate landing after a parachute jump. Among fracture cases 82% were got back to full flying duty; among burns, about 80%; and among nervous cases, 46%, although approximately 80% of the last group got back to flying duty of some sort.

#### Oxygen Supply

Air Marshal Whittingham said that the R.A.F. physiologists, in the early days of the war, designed an oxygen installation that was more than twice as efficient as the then existing set. This played an important part in helping pilots to gain mastery of the Luftwaffe in the Battle of Britain. Thus at 20,000 ft., if a flier was not getting oxygen, he became unconscious, if walking about, within 5 minutes, and at 25,000 ft., if sitting still, he became unconscious in 7 minutes. Without oxygen at 30,000 ft. he became unconscious in 2½ minutes and died in 15 minutes, and at 40,000 ft. became unconscious in half a minute and died within 5 or 10 minutes. Even at 10,000 ft., if oxygen were not taken, some effect was noticeable. Lack of oxygen produced symptoms resembling those of drunkenness; the man "felt himself to be at the top of the world, while every minute he was slipping under the table." The lecturer recalled that once on a flight from Iceland he wrote a paper during the voyage, and thought he had written it extremely well, only to find afterwards that it was ridiculous nonsense. The flight was at just over 12,000 ft. At 15,000 ft. there were visual disturbances and at 18,000 ft. hearing started to suffer; one suddenly realized that one was not hearing the engine. It had been necessary to indoctrinate air crews as regards their need for oxygen. He described and illustrated the oxygen apparatus and also the experimental chambers in which altitude pressures up to 70,000 ft. could be simulated.

#### Other Precautions

Finally Sir Harold Whittingham described the measures taken to deal with what was known as "bends"—a condition in which nitrogen bubbles formed in the blood and tissues, and various symptoms such as disabling pains in the joints, spots in front of the eyes, and a choking feeling were experienced. Only 10% of fit air crews under the age of 28 suffered from bends. The trouble was overcome largely by careful selection of personnel for special duties. Frost-bite had practically ceased to exist in the Air Force. Out of over 12,000 man-sorties there was only one case of frost-bite, and that was usually due to the negligence on the part of the individual. Improvements in the heating of aircraft had decreased the incidence of frost-bite tenfold in 4 years. Blacking-out occurred, not on account of speed but of changes in speed. Its avoidance was partly ensured by posture, so as to lessen the pooling of blood in the most

dependent parts, and by ensuring a high degree of physical fitness, including abstinence from alcohol and tobacco. Researches in connexion with altitude flying, explosive decompression, baling out from stratosphere heights, "blacking-out," cold, and night vision, including the counteracting of search-light glare, had materially helped our aviators both in the Battle of Britain and that of Berlin. He ended with a high tribute to the medical officers, professional, scientific, and executive, who had built up a medical service which he felt was second to none.

Lord MORAN, P.R.C.P., in proposing a vote of thanks to Sir Harold Whittingham, said that the greatest contribution the medical services had made to the R.A.F. was in the elimination of fear, since it was fear which paralysed the will power and lowered the morale.

### ENURESIS

A meeting of the Section of Urology of the Royal Society of Medicine was held on Feb. 24, with Mr. E. W. RICHES in the chair, to discuss enuresis.

Mr. T. TWISTINGTON HIGGINS said that enuresis was a symptom, not a disease. It was defined by Meredith Campbell as "the involuntary and usually unconscious voiding of large amounts of urine which occurs predominantly during sleep in the absence of organic disease of the nervous or urological system." The word "unconscious" seemed to exclude children who were deliberately dirty in their habits; these could not be excluded. The definition made no mention of age, but enuresis should not be spoken of until the child was 3½ or 4 years old. The ordinary healthy infant properly trained might be expected to be dry at 18 months, and if between that age and 3 the child was perpetually flooding, something was likely to be wrong. Spina bifida occulta must be considered. If the spines of all children were examined by x rays a proportion—estimated by some authorities to be 35%—would be found to have fusion defects, and, particularly if these were in the sacral area, spina bifida occulta might be the cause of enuresis. Approximately one case in ten would be found to have some organic disease of the urinary tract. The urinary tract lesions to be expected were almost all due to obstruction in the tract or infection, or a combination of the two. Careful examination should also be made of the external genitals. In girls vulvovaginitis was the commonest lesion. In boys the state of the external urinary meatus should be noted to ascertain whether it was contracted, ulcerated, or misplaced. One of the many traditions about the prepuce was that it must be amputated to stop bed-wetting, but he had never seen a prepuce, however tight, concerning which he was satisfied that it was a cause of urinary obstruction. Circumcision had no place in the treatment of enuresis. The condition of the bladder and the question of residual urine should be taken into account; a complete urine analysis should also be made. If this preliminary examination indicated a urological basis for the enuresis the child should come under treatment by the urologist, but if nothing abnormal was revealed the enuresis might be assumed to be functional. For functional enuresis institutional treatment of the proper type was invaluable, but not all children with bed-wetting could or should be treated in an institution. Sociological implications could not be ignored. The remedy was in better and securer homes and more intelligent, wiser, and less harassed parents.

Mr. H. P. WINSBURY WHITE said that during wartime a great increase in this condition was to be found in males, especially adolescent and adult males. He mentioned the value, after excluding extra-urinary conditions, of dilating the contracted urethra. As dilations would often have to be repeated it was wise to make this perfectly clear at the outset. The minimum period between dilations should be one month. Prolongation of the individual treatment by the use of the indwelling catheter for half an hour, and its removal before the patient awakened from the anaesthetic, could be carried out in certain cases. Chronic frequency of micturition when present usually improved quickly from dilatation.

### A Classification of Cases

Dr. W. SHELDON, as a practising paediatrician, said that enuresis was by no means confined to the poorer sections of the community: it was found in all social grades. In young children it was equally divided between the sexes; in the second half of childhood it was more common in boys than girls. Among 5,000 children aged between 5 and 10, and living in L.C.C. institutions, the incidence of enuresis was 5%. The classification he had found useful was: (1) cases associated with organic disease of urinary tract; (2) cases associated with disorder of health in some other system of the body; (3) cases associated with mental retardation; (4) functional enuresis persisting from infancy or reappearing in later years. In the first group there was usually diurnal as well as nocturnal enuresis or very great frequency of micturition. He had yet to see a boy whose enuresis could justly be attributed to phimosis. In the second group

many conditions might act as contributory factors, including disorders of the alimentary tract. Adenoid enlargement causing snoring and disturbance of sleep should be considered. He would reserve ephedrine for the treatment of enuretics whose condition was associated with allergic rhinitis. The use of drugs in the third group was universally disappointing. Something might be done with children in this group by bribery in return for a dry bed. In the fourth group it was useful to withhold fluid after tea and forgo any meal at bedtime; also to see that the child made a real effort to empty the bladder before going to bed, and was roused again after four hours to pass water. The attitude of the home must be encouraging. Praise for a dry night was better than scolding for a wet one. The raising of the bed so that the hips were above the level of the shoulders was sometimes useful. There was another group consisting of sensitive and intelligent children, who stood particularly in need of sympathy and encouragement; and, lastly, there was a small group of enuretics whom the war had brought into notice—those who intentionally wetted the bed to gain some advantage, such as transference to a fresh billet.

Dr. E. B. STRAUSS considered that enuresis belonged to psychiatry more than to urology. There was an atavistic pull-back to the original watery environment of the race. Another important factor was the extreme sensitiveness of the kidneys and bladder to emotional stimuli. He doubted whether spina bifida occulta was found more often among enuretics than among those who had developed normal bladder control. When pills and potions effected a cure they worked through their suggestive rather than their pharmacological properties. He had treated a group of children with a belladonna and potassium citrate mixture and a control group with burnt sugar only, and had got the same proportion of cures in both. Secondary enuresis might respond well to hypnotic suggestion. Mr. E. W. RICHES said that the finding of spinal fusion defects in a child with enuresis was not to be taken as an assumption that the defect was the cause of the enuresis. It was an indication for further investigation, which should be carried out with the cystogram and the cystomicrogram. By these means, with cystoscopy of course, it was possible to discover which bladders showed signs of disturbance of nerve function. If these cases were left he was sure that they would go in progressive stages to the complete incontinence of senility.

Wing Cmdr. J. C. AINSWORTH DAVIES found that indigestion was an important exciting cause. He had seen enuresis associated with gastric and duodenal ulcer, and when the ulcer improved the enuresis cleared up. One way to distinguish the malingering from the true incontinent was, on applying the urethroscope and fixing the floor of the internal meatus, to watch the roof, which ordinarily could not be seen unless the urethroscope was pulled right down to an angle of more than 45 degrees. If, however, the roof simply flapped into view he thought the case was likely to be one of true incontinence—that is to say, a relaxed internal sphincter. He also raised the question of the possibility of plastic operations. Mr. F. McG. LOUGHNANE said that he had had no experience of operating for enuresis. In examining these children with the cystoscope he had never found an abnormality in the bladder or neck of the bladder. If the children were of the age of about 12 he used the cystoscope without giving any local anaesthetic, and in a large number of these cases, whether as the result of suggestion or not, they did get better quickly. One of the most disappointing patients was a boy who at the age of about 14 was at a public school, where the matron was always holding him up as a bad boy on account of this habit. He had no abnormality. The speaker saw the boy when he was about 18 and sent him to a psychiatrist, who said that he had a fear complex which would take a very long time to resolve. He believed psychiatry to be indicated more than surgery in the treatment of these cases.

The Council of the Association of Clinical Pathologists prepared a draft memorandum in September, 1943, on a National Service in Clinical Pathology, and this was approved by a general meeting held on Jan. 28, 1944. The memorandum begins by stating that it seems likely that the national medical service of the future will be organized upon a regional basis, permitting a considerable degree of local autonomy within a framework set up by central authority. "Pathology is an integral and indissociable part of medicine, and as such must participate in any general reconstruction of the whole." Discussing pathology in relation to practical medicine, it says that public health or environmental pathology must continue to be the concern of Governmental bodies. Clinical pathology is the affair of those engaged in the diagnosis and treatment of sickness in the individual, and this latter branch of pathology, being the field of the Association of Clinical Pathologists, is the main subject of the memorandum. The views of the Association are then put forward under eight heads: scope of a national service, organization, attendance of patients at laboratories, domiciliary service, special clinics, status of clinical pathologists, blood transfusion service, and post-mortem service. The hon. secretary is Dr. W. H. McMenemey, Pathological Department, Royal Infirmary, Worcester.

## Correspondence

### Haemolytic Disease of the Newborn

SIR.—I have read with great interest the annotation in your issue of Feb. 19 on the eugenic and genetic aspects of the Rh factor, but I wonder whether the concluding statement that this genetic research has led "to the chance of timely recognition of a great danger and thus to prompt and successful treatment" is not too optimistic, since, although prompt treatment by injection of Rh-negative blood has improved the immediate prognosis, there is as yet no evidence that it will prevent the development of those dread sequelae of haemolytic disease of the newborn—kernicterus, cirrhosis of the liver, and (possibly) polyostic fibrous dysplasia.

It has been suggested that the danger of kernicterus is diminished if transfusion is carried out early, but in infants suffering from icterus gravis and hydrops foetalis we do not know for how long before birth the haemolytic process has been going on. Recently my colleague Dr. Baar has, as Haldane suggested, estimated the anti-Rh agglutinins in a pregnant Rh-negative woman—one of whose previous children had died from icterus gravis—and found that a marked increase in the titre of the agglutinins occurred at the seventh month. This observation suggests that destruction of the foetal blood began two months before the termination of the pregnancy. The occurrence of hydrops foetalis and the importance of haemolytic disease in the production of stillbirths are evidence that the disease may have such a long intra-uterine course that treatment will not be universally successful; moreover, since cirrhosis of the liver has been found in stillbirths which show evidence of haemolytic disease it is clear that cirrhosis may be present when the child is born alive. Possibly kernicterus might be prevented if labour were induced or Caesarean section done at the time when the great increase in the titre of anti-Rh agglutinins in the mother's blood occurs; but in the case already mentioned this would have meant the added risk to life of such a degree of prematurity that the child might be almost classed as non-viable. Actually this mother was allowed to go to term and an exsanguination transfusion with Rh-negative blood carried out on the infant within a few hours of birth.

It may be thought that kernicterus is so rare that its occurrence may be discounted; but it is only necessary to see one case to realize that, until this complication can be prevented, the ultimate prognosis of icterus gravis can never be regarded light-heartedly however successful its immediate treatment may be. In the past, when attention was only paid to ABO grouping in transfusion, its incidence has been about 8 to 10%. There are certain symptoms—excessive somnolence, convulsions, and a high-pitched cry—which suggest the occurrence of kernicterus, and if these are present I believe it is better to leave the child untreated in the hope that it will not survive.—I am, etc.,

Birmingham.

LEONARD G. PARSONS.

### Control of Pharmacological Products

SIR.—The plea made by Mr. Robert Taylor (Feb. 26, p. 307) for a control of pharmacological products deserves a wider publicity and the support of our representative medical councils. He exposes the technique by which manufacturing chemists select a product possessing a specific therapeutic action, modify the formula in a small way, and exhibit the newer design under a fancy name. Taylor sees signs of this exploitation, so obvious in the case of barbiturates, being applied to the sulphonamides. How much longer is the medical profession to tolerate and condone this travesty of scientific therapeutics? When a certain digitaline pill gained a reputation in the treatment of heart failure, eight other manufacturing chemists prepared a digitaline product. A controlled clinical trial of these separate brands having the same distinctive colour and the same peculiar dosage showed a wide and unsafe variation in their therapeutic effects. Another miscarriage of our scientific

aims in treatment is instanced by the many remedies recommended for angina pectoris and high blood pressure. The merits of such potions are exalted in the daily press, on the backs of motor-buses, and even on the interleaves of medical journals. The Therapeutic Trials Committee of the Medical Research Council undertakes to test remedies submitted voluntarily by any drug house, but there is a need for a medical research tribunal which would control all proprietary preparations and release none for therapeutic purposes until a beneficial action has been established after clinical trial.

In the evaluation of a remedy three postulates should be accepted as forming a statutory standard of efficiency. First, the drug must retard the progress of a disease and/or relieve its symptoms. Secondly, it must show this specific action consistently and in the majority of patients, and in this way demonstrate an effect distinct from and superior to that which might take place as a natural periodic variation in the course of the disease in the absence of treatment or during placebo therapy. Thirdly, it must produce its beneficial effects without toxic symptoms. Not until the Ministry of Health invests such powers in a medical research tribunal will the haphazard selection of medicines for our patients give way to therapeutics founded soundly on scientific assay.—I am, etc.,

London, W 1.

WILLIAM EVANS.

### Functions of Industrial Medical Service

SIR.—In answer to Dr. D. Kenwyn Harris's excellent letter (Feb. 26, p. 304), we are sorry that we did not make the question he raises clear beyond doubt in our article.

We work in the most intimate manner with local practitioners, the public health department, and the local hospitals. As soon as any patient presents herself to the medical department of the factory she is referred either to her own doctor or, if she so desires, to the works clinic. The patient's wishes are the only consideration. If she chooses the works clinic she is first examined and then referred to her own doctor with a covering letter giving full details of findings and suggesting a line of treatment. With the approval of the doctor, who is usually relieved that we will undertake the routine work on his behalf, the patient is then supervised by the clinic, treated if necessary, and booked for hospital, evacuation centre, etc., according to her choice.

Exactly similar methods are employed for gynaecological cases. We emphasize that only treatment of industrial conditions and emergencies is carried out without the approval of (1) the patient, (2) the patient's doctor, (3) the hospital or clinic, or (4) the public health authority, as the case may be. Perhaps we have been fortunate, but the relations existing between all the above and ourselves are of the most cordial nature. The last sentence of Dr. Harris's letter expresses the feelings we had in the matter until recently, but our investigations have convinced us of the need for assisting gynaecological cases, especially where the demand for labour for vital purposes made it essential to keep "all hands on deck."—We are, etc.,

J. V. O'SULLIVAN.  
L. B. BOURNE.

London, N.5.

### Physics in Medicine

SIR.—I am sorry if Dr. Mumford finds that my letter on emulsions is a criticism of dermatologists or of those who dare to sign prescriptions. The intention was to draw attention to certain facts which might, perhaps, give a better explanation of what happens in practice. Adsorption phenomena are of such general daily application that we are apt to overlook the science in it. Little is really known of the manner in which medicaments get into tissues, unless we are satisfied with phrases which are quite correct but are only general statements. Indeed, the recent paper by Lionell and Thomson (Nov. 6, 1943, p. 572) shows that there is doubt whether some of the drugs commonly used have any effect at all. We know that thallium salts will cause every hair to drop out (provided that the patient survives), but there is no real knowledge of how or why it does so. Quinine has been used for some centuries, and we rely on it to a great extent for controlling the worst disease known to mankind.

Much work has been done on it and the literature is very great, yet we are still completely ignorant of how or why it acts, and there is even considerable doubt exactly where it exerts its influence. Opium has come down to us from the ancients, and we still do not know how or why morphine affects some cells more than others, why there is that special selection: only the general statement that it affects metabolism of those particular cells.

As to the "physical rules governing such contact" modern textbooks deal with that subject and many individual papers are concerned with it. The best-known and commonest example is the function of the red blood cells, where it is recognized that physical properties play an important part. It is known that Donnan's equilibrium theory holds, but the details are obscure. Much the same is true of botanical physiology. Again, speaking generally, the blood may carry the same materials to adjacent tissue cells, yet each cell may select different substances from it. But this general statement is not true if one goes into details, for the "blood" does not usually supply tissue cells *directly*—never in the skin—only in certain cases. More usually most cells of the body rely on serum extravasated and make their selection from that serum. All cutaneous cells do so, but we do not know how or why the cells make such selection. The most probable explanation is a physical one. We do know that the extravasation is due to physical conditions—*pH*, etc.—but I have heard no explanation of how or why it acts.

The truth is that most of us (and I am one) are so ignorant of mathematics that we tend to take refuge in denying and decrying the whole thing. It is the easiest way out. I am one of the antiquated group who are trying to creep out of that pit of stagnation; and it is just that effort which makes me realize how much I miss and to what extent medicine, even the practice of it, fails or lacks simply because we funk the *dx/dy* business, de Moivre's theorem, and so on. And the interesting thing is that there does not seem to be any actual necessity to know about *dx/dy*, the square root of minus one, the squiggles used, so long as medicine accepts the deductions made by the physicists. To me the real interest in Dr. Mumford's letter is that it indicates how strong is the repugnance to getting out of a groove, even among dermatologists. If only it were realized what a great field is open in this direction, and also how useful it might be in practice, we should soon get more knowledge on the "physical rules governing contact." There is no necessity for any physical chemist "to arise," for there are many at work, though there are too few of them, but very few practitioners who dare to consider them, far less to attempt to apply them in practice.—I am, etc.,

Kingston Hill, Surrey

W. F. COOPER.

### Tonsillectomy in Children

SIR.—Mr. E. Carew-Shaw writes that there is a "small minority" in the medical profession who hold the view that tonsil and adenoid removal in children is at the best useless and even may be harmful." I have never heard of anyone who has stated that this operation is "at best useless," and should be obliged if he would let me have the reference to the articles which "have appeared in various medical journals" which make this opinion "obvious" to him. "Significant" I agree. There are those who hold that this operation "even may be harmful," but I doubt whether those who hold this view are in a "minority," and I am confident, if they are, that it is not "small." Just the opposite. The significance lies in the growing body of men and women who believe that it is time strictly to limit this operation to "criteria" that will produce the excellent results that with him I find it gives, though that these are "well known" I doubt, or the operative activities of the many would be limited to the few in which it occurs.

I am one of those who taught Mr. Carew-Shaw's generation the aphorism about "the tonsils, all the tonsils, and nothing but the tonsils," but I now believe that the physiological movements of the palate and fauces are less impaired when a little bit is left behind at the lower pole. I am not prepared to go back upon my teaching, because I cannot say in which patient

it will continue to do harm and necessitate a second operation more difficult and more damaging than the first. I prefer to limit the damage that I do by a careful selection of cases in the first instance; and for this nothing is of greater value than the long waiting list. Though the operation is never an urgent one it is probable that if after waiting for six months no harm has come to the child the advice given in the first instance was wrong. There is no need for laryngologists to "struggle with nearly overwhelming lists of children for tonsillectomy." They should use their lists and review monthly all those patients that have been on them for six months. They will thus save themselves much unnecessary work, the parents much anxiety, and the children much pain and harm. I do not believe that any surgeon can guarantee that he will do no harm by any tonsillectomy that he performs, however perfectly and by whatever method. The movements of the fauces and palate are so delicate and so numerous that any fibrosis will interfere with them, and whenever scarring is observable the damage is definite. The effect of this upon the physiology of the upper respiratory tract is far-reaching, though difficult to determine and not previously sufficiently recognized.

Mr. Carew-Shaw makes a grave accusation against himself when he suggests that he gives more care and attention to his patient when he is paid by a specific fee than when he is paid by a salary, sessional payment, or capitation grant. This is a matter that those who deal with the N.H.I. have been struggling with since its existence. It is to be regretted that some doctors do, and thereby bring disrepute upon those who are striving to give the same service to all. I do not believe that any mother should ever be expected or allowed to hand over her child for this operation with its attendant dangers after less than a quarter of an hour's discussion with the surgeon. I further believe that if he gives that amount of time to each case he will so cut down the number in which he advises operation that he will have more time rather than less upon his hands. It is a remarkable thing that when an operation has been advised the administration will always find the time, accommodation, and personnel for its performance, but that no such administration has as yet been set up which will give that minimum of a quarter of an hour between the parent upon whom the responsibility for decision rests and the surgeon in whose hands the responsibility for advising the operation is finally put.—I am, etc.,

Guy's Hospital, S.E.1.

T. B. LAYTON.

### Infant Mortality in Scotland

SIR.—In contrast to the Orr Committee, which has studied the problem of Scottish infant mortality from its academic, professional, and administrative eminence, may I, having studied and experienced it from below, venture on this constructive criticism of the committee's report.

The Orr report shows that the high infant mortality in Scotland is due to the low standard of living of a large part of the population, yet its main recommendations do not counteract the adverse factor of poverty itself. The experience of poverty is not confined to bad housing and poor diet, although these are important evils. There are other contributory deprivations, such as inadequacy of clothing, footwear, bedding, furniture, and cooking utensils, all of which combine to induce frustration and mental apathy.

I. *Rehousing*.—We have had rehousing schemes for almost twenty years; although they have dealt only with a small part of the population in slums, it may be assumed that the experience of these is representative of that of rehousing on a national scale. Rehousing abolishes overcrowding and reduces infection, but these benefits are lessened (a) when economic necessity restricts a family in the use of its house either by fuel consumption or by the subletting of rooms; (b) when a family has to use a common towel. In a review of the effects of rehousing over a five-years period in Stockton-on-Tees (McGonigle and Kirby, 1936) it was found that in the rehoused population the infant death rates were not significantly less than those in the slum areas, because the rehoused families had continued to live under the handicap of poverty. The Orr report states that in Glasgow good results have been obtained by rehousing. It is obvious, however, that so long

as the environment of poverty persists the best results cannot be achieved. Can a city with the highest infant death rate of the English-speaking world be content with less than the best?

2. *Diet*.—In Part III of the report (the Feeding of Mothers and Infants) it is stated that the inadequate diets of pregnant and nursing mothers among the poor are associated or correlated with the toxæmias of pregnancy, with premature birth, stillbirth, and unsuccessful lactation; yet the recommendations of the report are most vague with regard to diet. One would have expected the committee to endorse its belief in such a grave and sweeping statement by a more vigorous recommendation, such as the immediate provision of adequate meals for necessitous expectant and nursing mothers (so far as food resources permit). Sir John Orr, in his book *Food, Health, and Income*, has shown that, dividing the population into groups according to income, the higher the group the better the diet it instinctively purchases: surely this is an argument in favour of raising the economic level of the poor.

3. *Child Welfare Services*.—The report recommends their extension and improvement, and the further improvement and training of health visitors and medical staff. The health visitor of to-day is a capable (but dispirited) woman who is a State-registered nurse; many are, in addition, certified midwives, and others may have undergone special training in health visiting. At the present crude stage of the problem the qualifications of the health visitor are largely wasted, as her work consists chiefly of imparting the most elementary principles of hygiene and infant care. In this she fails—as indeed does the whole medical personnel of the child welfare service—not because of ignorance of the niceties of nutrition but because her knowledge is a useless weapon against the armour-plating of poverty.

The report also states that "clinic premises are often poor, ill equipped, and overcrowded." This is very true, but so long as poverty persists, any expenditure on the construction and equipment of specially designed clinics is wasted money. I have personal experience of conducting a clinic under the most advantageous conditions in a building designed for that express purpose. It was of no more value than the most faulty premises in a slum because of the poverty of the rehoused population for which it catered.

The Secretary of State for Scotland recently announced in Parliament that the infant mortality for 1943 had fallen to 65 per 1,000 live births, the lowest yet recorded for Scotland. He attributed this to a reduction in unemployment figures from 11.5% in 1939 to 1% in January, 1944, and to the resulting increased purchasing power. Thus we see that prosperity has struck a big blow at Scottish infant mortality. It is the common experience of child welfare workers that prosperity can transform an apathetic parent into an alert and responsive one. Encouraging as these figures are, there must still be many families which have not participated in this economic well-being.

From the Orr report we learn: (a) that the high birth rate of the Scottish poor is at a level desirable for the population as a whole; (b) that a high birth rate is not necessarily correlated with a high infant death rate, as in Scotland; (c) that Holland and New Zealand with high birth rates (and a higher standard of living) avoid this wastage of infant life. Is there not therefore a clear indication for recommending the speedy provision of adequate family allowances (first sponsored by the Beveridge report), which would give prosperity to that part of the population most sorely in need of it?

In conclusion, the Orr Committee has discovered the main truths concerning the high infant death rate in Scotland, but its recommendations have not kept pace with its findings.—I am, etc.,

Dyce, Aberdeen.

MARGARET S. M. MCGREGOR.

### Extrinsic Renal Factor

SIR.—With reference to an article in the *Journal* of Sept. 18, 1943 (p. 356), on pituitary hypothyroidism with impaired renal function, by Drs. Beaumont and Robertson, the association of these two factors is noted as "not previously referred to in the literature." While this statement is true so far as these observers are concerned, it may eventually be of some his-

torical interest to point out that the actual discovery of the "extrinsic renal factor" was made by a group of research workers at Auckland, N.Z. The preliminary articles appeared in the *New Zealand Medical Journal* in April and June of 1941. Subsequent articles (5M and 5T) were rejected by both the *New Zealand Medical Journal* (June 6, 1941) and the *British Medical Journal* (March 23, 1942) on the grounds of lack of space and the paper shortage. The Medical Research Council of Great Britain acknowledged their receipt on June 7, 1942.

In these and subsequent articles (5A, 5P, 5H, and 5R), which are all included in our book entitled *The Electrical Factor in Metabolism*, by Abbott and Fowler, the association of this peculiar type of renal insufficiency of function with an endocrine dyscrasia is demonstrated by means of the Fowweather urea clearance technique. A description, with many illustrative cases, is also given of the new method of augmenting renal function by means of water that has been physically altered as the result of its exposure to the radiation and the electrostatic field supplied by the "scalebuoy effect."

We have suggested that a similar physical alteration in the water molecule is brought about by the metabolism of the life process with its endocrine control. The articles also deal with this new radio-electric technique in relation to a variety of clinical phenomena, such as the sedimentation rate of blood, pigmentary structures, the urea mechanism and excretion, the immunity mechanism, nephrosis, menstrual dysfunctions of the endocrinopathic type, and the hydrophilization of colloid structures in relation to a variety of phenomena such as asthma, glaucoma, fibrositis and nodule formation, diabetes mellitus, prostatic hypertrophy, acne vulgaris, and symptomatic effects of the  $\alpha$ -bacterial rheumatic type.

Only a limited number of the above-mentioned book are being printed for circulation among similar research groups in Australia, Canada, Great Britain, and the U.S.A. with the object of co-ordinating the work. It is also felt that much further confirmation of the various concepts, such as that provided by Beaumont and Robertson in the case of the extrinsic renal factor, is necessary before the work could be added to the general literature on metabolism. The authors would, however, be prepared to supply a copy of the book gratis to similar interested research groups.—I am, etc.,

Epsom, Auckland, New Zealand

W. N. ABBOTT.

### Sulphaguanidine and Renal Damage

SIR.—I have read with great interest Dr. H. G. Smith's article on sulphaguanidine for Flexner dysentery (Feb. 26, p. 287). He states that the high incidence of toxic rashes suggests the need for care in dosage, but my experience is that it is more important to guard against kidney damage, even when using sulphaguanidine in moderate dosage.

In the hospital in which I am working 25 adult cases of bacillary dysentery were treated with sulphaguanidine during the past year. Each patient received 51 g. in the following dosage: 9 g. daily for 3 days, then 6 g. daily for 4 days. The fluid intake was at least 5 pints per day. Urinary examination during the course showed crystals and red blood cells in 14 patients, and crystals alone in 4 patients. A morbilliform rash developed on the tenth day in 3 cases where crystals and red blood cells had appeared in the urine 4 to 6 days prior to the rash. This suggests that daily urinary examination is advisable when giving sulphaguanidine. These crystals are colourless, rectangular, and variable in size. They are easily recognized by their uniform shape, and, in addition, give the sulphonomide colour reaction.

I would be interested to hear whether Dr. Smith's cases showed any evidence of renal damage before the appearance of the toxic rash.—I am, etc.,

Whittingham, Preston.

J. H. S. WHYTE.

### Nutritional Neuropathies in Spain

SIR.—In the latter part of the article appearing in your issue of Feb. 26 the statement is made: "The appearance of classical pellagra in Madrid, where the population never ate maize, put nicotinic-acid deficiency on a firm aetiological footing: quick response to treatment with nicotinic acid clinches the matter." This appears to be very ambiguous. If it be intended

to suggest that this is the first time a population has developed pellagra when partaking of a non-maize diet it is incorrect. That this could occur was proved thirty years ago.

It is also not very clear what treatment with nicotinic acid "clinches." The results of treatment with this substance have been known for years. The impression is also given that Peraita's observations are all new, but the conditions he has described, though new to Spanish observers, were described many years ago.—I am, etc.,

London, W.1.

HUGH S. STANNUS.

### Chloroform Anaesthesia

SIR,—Dr. H. Parry Price (Feb. 19, p. 263) advocates a "crusade" against the use of chloroform. Such a crusade has been going on to my knowledge for 25 years and probably longer. As a student I was taught *not* to use chloroform, instead of *how* to use it. I learned to view chloroform in its correct perspective from an old G.P. who always uses chloroform and nothing but chloroform, and does not, in fact, know how to use anything else but chloroform. He pours chloroform on the mask as most doctors do ether, saying to the patient, "Take good deep breaths, and the deeper you breathe the sooner you will be asleep"; and in over 40 years of general practice he has never had a catastrophe.

The chloroform-phobia that afflicts our profession is astonishing. Of course chloroform is a dangerous drug; and what are we trained for if not to learn how to use dangerous drugs? If the toxicity of chloroform is assessed in relation to its greater power as an anaesthetic I doubt if it is any more lethal than ether. One must not, of course, give chloroform to a toxic, cardiac, or hepatic patient; nor must one give ether to a bronchitic patient. Certainly chloroform can cause liver damage; so can ether cause pneumonia. Chloroform has caused deaths from heart failure on the operating table; and I have seen an apparently normal healthy woman of 34 die at the end of an operation for removal of fibroids, having had nothing but pure open ether, for no reason that anyone could discover. Of all the foul and revolting anaesthetics commend me to ether (I have myself been put to sleep by pure ether on one occasion and pure chloroform on another); the spectacle of a house-surgeon and three nurses struggling with a coughing, spluttering, vomiting, fighting patient in the attempt to anaesthetize him with ether is not one of which our profession can be proud. Moreover, with a patient accustomed to alcoholic drink ether may be useless. I have in mind one whom I would defy any anaesthetist, however skilled, to put to sleep with open ether, let alone reduce him to surgical anaesthesia.

I read that "the expert has abandoned chloroform altogether." Passing over the implication that no G.P. is "expert" and assuming that your correspondent means the consultant anaesthetist in hospital, I am aware that the latter now has a predilection for an apparatus that looks like a cross between an oil refinery and a B.B.C. transmitter, in which the cyclopropane, like the music, "goes round and around and comes out here," which is a lovely toy for those with a taste for gadgets; but the G.P. can hardly carry a hundredweight and a half of machinery in his waistcoat pocket, and consequently the G.P. uses chloroform, and will continue to use chloroform until something equally powerful, convenient, pleasant, and, without, less toxic is discovered.—I am, etc.,

Saltash

W. H. SPOOR.

### Fainting in Blood Donors

SIR,—The authors of this report to the Medical Research Council (Feb. 26, p. 279) are unable to draw any conclusions from an analysis of the data given, except to state that 45% of the donors who fainted gave a history of having done so on some previous occasion. They grouped them in ages, sexes, civil status, menstrual, married and single, following classical aetiological procedure. But this failed to reveal the secret of the fainting donor. If one examines the symptoms described and were asked to make a diagnosis one would report as follows. Excluding convulsions these are cases of autonomic nervous system disturbance. It appears possible

that the fainting donor is an example of a psychosomatic reaction of the anxiety type. The aetiological factor would be a group or system of ideas connected with blood or injury, or a past traumatic experience long forgotten which, when combined with the bleeding technique, would produce an anxiety reaction. I am bleeding donors who are also my patients, and from my small personal experience fainting and collapse occur in persons who have experienced psychosomatic disorder during difficult life situations before.—I am, etc.,

Grange-over-Sands.

DUDLEY MULKERN.

SIR,—The writers of the report to the Medical Research Council appear puzzled as to the factors behind this condition. Forty-five per cent. of the donors give a history of having fainted on a previous occasion—e.g., when giving blood or at the dentist. It is well known that many people are afraid of having operations performed on them. I suggest that the majority of the patients, probably all, were frightened. As a result the symptoms and signs ranging from feelings of warmth, pallor, or dizziness to vomiting, loss of consciousness, etc., were produced via the endocrine-autonomic system.

Observation of the patients for the other usual objective evidences of fear, together with an adequate feeling relationship between the patients and those in charge of the bleeding, would have made this point clear. There has been some discussion in your columns recently about the part played by psychological medicine in the future curriculum. A knowledge of the bodily changes produced by emotions should certainly be more widely spread.—I am, etc.,

S. D. MITCHELL.

E.M.S. Psychiatrist.

### Preventing Necrosis of the Skull

SIR,—I am interested in the correspondence on the operation of drilling holes in the external table to let the granulations grow through. I did this operation in the spring of 1901, when I was house-surgeon at the old Royal Infirmary at Newcastle-upon-Tyne. I did it on the instruction of my chief, the late Prof. J. Rutherford Morison. I always thought it was an original idea of his, and he should have the credit for it. I hope this will fill the gap in Prof. Grey Turner's memory. He was surgical registrar at the time, and at a later date trephined the same patient.—I am, etc.,

Sunderland.

R. H. DIX.

### Just Suggestion?

SIR,—Dr. J. Frankland West in his letter (Feb. 19, p. 267) seems to have come to the inevitable conclusion about what he calls his "fibrositis"—that many things will relieve the symptoms, but that current medical practice can do nothing to remove them once and for all. I would suggest that *just* so long as the medical profession fails to take into account the work of F. Matthias Alexander, just so long will they be defeated by these and similar problems. Alexander has shown by his work that our general functioning is profoundly influenced by the way in which we use ourselves in all our daily activities, and that by constantly misusing ourselves in the simple activities of living we are bringing a constant influence for ill to bear upon our general functioning. Until we realize this fact our diagnosis is bound to be incomplete, and we demonstrate our lamentable ignorance when we content ourselves with uttering the latest catchword of medical terminology. Dr. F. G. Crookshank has written: "Diagnosis, which, as Mr. Bernard Shaw has somewhere declared, should mean the finding out of all there is wrong with a particular patient and why, too often means in practice the formal and unctuous pronunciation of a Name which is deemed appropriate and absolves from the necessity of further investigation."

Dr. F. M. R. Walshe, in his stimulating article (Feb. 5), has given Crookshank's work the recognition it deserves. It is inevitable that Alexander also will eventually get recognition from those concerned with medical education. Meanwhile, Dr. West will perhaps find that a study of Alexander's work will give him a more hopeful approach to his problem.—I am, etc.,

London, S.W.1.

WILFRED BARLOW.

## Obituary

J. W. H. EYRE, M.D., M.S., F.R.S.E.D.

With the passing of Prof. John William Henry Eyre bacteriology in this country has lost one of its outstanding personalities. He was born in 1869 and, after being educated at first privately and then at the Whitgift Grammar School, entered Guy's Hospital Medical School as a student at the age of 20. He quickly qualified M.R.C.S., L.R.C.P., and graduated M.B., B.S. of Durham University. Within a few years he had also obtained both the M.D. and M.S. degrees, and had meanwhile received his first appointment to Guy's Hospital (1894)—namely, that of ophthalmic assistant and registrar. For a time he devoted himself mainly to these duties. But the remarkable aptitude which he showed later for laboratory investigation almost at once declared itself, and his work, carried out under Washbourn's influence, on the normal bacteriology of the eye and a series of papers on tuberculosis of the conjunctiva stand as classics to this day. At this time the potentialities of medical bacteriology were becoming obvious to everyone, and, increasingly attracted to the new work, Eyre in 1899 took up the post of bacteriologist and lecturer at Charing Cross Hospital. Coincidentally the Council of the B.M.A. awarded him the first Ernest Hart Memorial Research Scholarship, and then, within three years, he returned to his old hospital, succeeding Dr. Washbourn as bacteriologist to Guy's.

The present generation will scarcely credit the smallness of the space considered in those days adequate for the bacteriology of a large hospital. Eyre had first to work in minute quarters near the old bakery. But, quite unaffected by this handicap, he at once began vigorously to help in the advancement of his subject. In 1905 we find him co-opted by the Royal Society to the Advisory Board of the Commission on Mediterranean Fever, acting as chairman of the working party in Malta and making valuable contributions to the final report. Over the same period he did much work in improving the prevailing laboratory methods, culminating in his famous book, *The Elements of Bacteriological Technique*. His papers on pneumonia and pneumococci and the causes of institutional dysentery were also noteworthy. Such activity was bound to call for enlargement of his laboratories, and in 1910 a large new bacteriological department was developed at Guy's entirely to Eyre's own design. Accommodated in buildings adjoining the older surgical wards, these new premises formed for many years one of the show departments of the hospital, remaining a model of their kind and successfully meeting every new demand upon them right up to the time of his retirement in 1934. The systems which Eyre devised for handling records and accounts, as well as the actual technical work, have formed the basis of much subsequent routine laboratory development, and it is remarkable that an organization so firmly standing the test of time should have been designed when the science itself was still so very young; proof, indeed, of Eyre's exceptional foresight with regard to his specialty. Appreciation of his work was shown by appointments as Erasmus Wilson Lecturer and a Hunterian Professor at the Royal College of Surgeons and Milroy Lecturer before the Royal College of Physicians. In 1920 the title of professor of bacteriology in the University of London was conferred upon him, Eyre having already held a readership in the subject for many years. Just previously, throughout the last war, he had acted as bacteriologist to R.A.F. and other wartime hospitals, and was a member of both the Trench Fever Committee of the War Office and the Chemical Warfare Committee of the Medical Research Council. As an examiner he was excellent; always fair, always courteous. For the University of London he acted in State medicine from 1911 to 1915 and in bacteriology between 1923 and 1928. For the Royal College of Surgeons he examined in public health from 1917 onwards and in tropical bacteriology from 1911 to 1920. A most efficient chairman, whether of scientific meetings or administrative committees, his activities in this direction seemed endless. Notably he was president of the Royal Microscopical Society (1920-1), of the Hunterian Society (1939-42), and of the Royal Institute of Public Health and Hygiene (1942). He had also served as president of the

Section of Bacteriology and Pathology at the Annual Meeting of the British Medical Association in 1913.

Eyre's interests and reputation extended far beyond his own country, and he was an active corresponding member of both the Société de Pathologie Exotique and the Société de Pathologie Comparée. His editorship of the revised English translation of *Experimental Bacteriology*, by Kolle and Hetsch, was masterly. Not all his work was, however, experimental: much of it had very direct clinical bearing, and his power to apply his laboratory research to the needs of everyday medicine is well illustrated by his collaboration with Dr. Bosanquet (1909) in a small but very practical book *Serums, Vaccines, and Toxins in Treatment and Diagnosis*. Even then one has not catalogued all his activities. For a great many years he held the appointment of bacteriologist to the Worshipful Company of Fishmongers, which accounts for a series of reports upon the bacteriology of the various edible molluscs, the most notable being, perhaps, on the oyster in relation to public health in 1924. His methods of systematic prevention of pollution of the nation's supplies must have prevented many epidemics. In addition to all this he was throughout his long life a very prominent Freemason, reaching high office and living according to the very highest traditions of the craft. As seen from the dates already given advancing years did little to reduce Eyre's activity, and his career is remarkable in extending continuously from the very earliest days of clinical bacteriology right down to the present time. It must have been a great satisfaction to him to see how many of his own earliest technical innovations would obviously long survive him. There is no doubt that practical bacteriology as we know it to-day owes much to Eyre's inventive genius.

A man serving so long as 32 years on the staff of one teaching hospital must inevitably have appeared in somewhat different lights to succeeding generations of Guy's men, but from beginning to end everyone knew, loved, and honoured "Johnny" Eyre. Whether one met him as colleague, student, or patient, there was something so dynamic in his personality that its origin in one of such minute stature always remained somewhat of a mystery. His energy was extraordinary and devoted unsparingly to every task or problem he met. Success never spoiled him; he was entirely without conceit. One so small was fated to be the student caricaturist's joy, and the *Gazette* of his hospital carries many humorous but always kindly reminders of at least one characteristic which he shared with the minute beings he delighted to study. No one ever asked his help in vain, and it is doubtful whether one has ever heard more expressions of true appreciation and affection than came from his many friends who attended the farewell dinner given to him when he retired from Guy's. Those who actually worked with him would go further. There are many to-day engaged in the laboratory aspects of medicine who owe much not only to Eyre's inspiration but to his unflinching interest in the welfare of everyone, from the highest to the lowest, who ever worked in his department. For his immediate colleagues a great man's memory will indeed outlive his life. F. A. K.

Dr. T. BLANCHARD SELLORS writes: Prof. Eyre's friendship was a privilege I enjoyed for forty years, since, in fact, the time he was making up his mind to give up eyes for "bugs." In those days few, if any, hospitals had a special chair in bacteriology, and for a few years he acted as assistant to Dr. Washbourn, then in charge of public health at Guy's. He was given the new appointment of bacteriologist at Charing Cross, returning to Guy's when a similar post was created there. He was a tireless worker, and practically died, as he had lived, in harness: no amount of persuasion could induce him to retire. His spare time was chiefly devoted to Freemasonry, wherein he was a Past Deacon of Grand Lodge and Past Master of the Grenadiers and Aesculapius Lodges. We worked together for three years in preparing the history of the first named for its bicentenary in 1939, and though the festival had to be abandoned on account of the war, the volume remains for me as testimony to a frequent and very friendly collaboration. Others can write with better knowledge of his professional attainments, but only those who knew him could tell of the happiness of his family life, the worth of his friendship, and the value of his varied experience. Few of his colleagues, by the way, are aware that he was a successful journalist before adopting medicine as his life's work.

WILLIAM ROBINSON, M.D., D.P.M.

Dr. William Robinson died at Tankerton on Feb. 21. He was the younger son of William Henry Robinson, was born at Skipton, Yorkshire, on Oct. 19, 1888, and was educated at Skipton Grammar School, proceeding to the Medical School at Leeds University. There he had a very distinguished career

as a student, obtaining many prizes and honours, including the gold medal for anatomy in his year. He graduated in medicine with honours in 1911.

Immediately after qualification he undertook the "summer locum" at the West Riding Asylum, Wakefield, and this temporary appointment was destined to influence his whole life, as previously his intention had been to follow a surgical career. After a few weeks in private practice he returned to Wakefield as assistant medical officer on the permanent staff. Hard work and scrupulous care earned him rapid promotion. In 1913 he obtained the D.P.M. of Leeds, becoming one of the earliest holders of this diploma from that teaching school, and he followed Henry Devine as deputy to Prof. J. Shaw Bolton, at that time medical director. When war broke out in 1914 he immediately offered his services, was fortunately appointed a Command Psychiatrist, and at once went over-seas. He served in this capacity in France until the end of hostilities. He returned to his duties at Wakefield Mental Hospital in 1919, and in 1920 obtained the M.D. degree of Leeds University. He later published his thesis, *The Future of Service Patients in Mental Hospitals*; this was regarded for some years as a classic and quoted on many occasions. In the same year he was appointed at the early age of thirty-two medical superintendent at Brentwood Mental Hospital. After five years' strenuous work there he was appointed medical superintendent at the City of London Mental Hospital, Dartford, a position he resigned on medical advice on Nov. 1, 1943.

His work as medical superintendent at Brentwood and Dartford was indefatigable, and both institutions owe much to him. His first consideration was for the welfare and comfort of the patients under his care; they came first, and next he valued a contented and happy staff, his efforts always being for those with whom and among whom he worked, starting with the most lowly. While at Dartford he had many outside interests; besides being consultant psychiatrist to several of the surrounding general hospitals he was an active member of the local hospital committee and medical adviser to two other general hospitals. A considerable amount of Robinson's best work will never be known; much time and labour, much advice, he gave "behind the scenes." To those who knew him some of the terms used in the 1930 Act were already familiar.

William Robinson joined the B.M.A. in 1926. He was secretary of the Dartford Division from 1937 to 1939; chairman of the Division from 1929 to 1931, and from 1935 to 1936; and president of the Kent Branch from 1932 to 1933. He was secretary of the Local Medical War Committee from its inception until October, 1943. His duties in this latter position were not always easy, but his tact in handling difficult matters was appreciated both locally and centrally. By his early passing there has been lost to medicine a physician, a psychiatrist, an administrator, all of outstanding merit.

Dr. JAMES PRIOR, formerly a well-known and much-respected practitioner in Heckmondwike, died at the end of last year at Adel, Leeds. He was a native of Dewsbury and studied medicine at the Leeds Medical School and St. Thomas's Hospital, London, qualifying as M.R.C.S., L.R.C.P. in 1894. Returning to Dewsbury he served for 4½ years as resident-house-surgeon at the Infirmary, and in 1900 began private practice at Heckmondwike. He spent 23 years as medical officer and public vaccinator for the district, and was for a long period medical officer to the Staincliffe Infirmary and surgeon to the Dewsbury Infirmary. Dr. Prior joined the B.M.A. in 1903 and held office as chairman of the local Division in 1926-7; he retired from practice in 1933. He did good work for the St. John Ambulance Brigade and had many interests outside his profession.

The death of Dr. R. MUZIO WILLIAMS on Dec. 14 came as a great shock to his many friends, for, in spite of his 84 years, he always appeared to be full of youth and energy, and indeed had been in London at a luncheon of the United Hospitals Club only a few days before. Born in 1860, he was the fourth son of Henry Owen Williams, D.L., J.P., who was High Sheriff of Tre-Ardur and Tre-Castell, Anglesey. At St. Thomas's Hospital he gained the first entrance science scholarship in 1879. He qualified M.R.C.S. and L.S.A. in 1884, L.R.C.P. in 1885, M.B.Lond. in 1887, and M.D. in 1888. In 1885 he was appointed resident house-physician at St. Thomas's, and from 1886 to 1887 he held the post of resident at the London Fever Hospital. The next year found him as a ship surgeon in the *s.s. Magellan*, in which he served for eight months; and in 1889 he became medical officer to the Florence Nightingale Hospital for Gentlewomen. In 1881 he married and settled down in general practice in the area round Hyde Park, where he continued until his retirement. "Muzio"—as he was known to his friends—was the ideal type of general practitioner, equally at home with and acceptable to peer or pauper, man, woman, or child; and was as dearly loved by his patients as by his

friends, many of whom will remember him for his humour, his unfailing kindness, and the thoroughness he displayed in everything he undertook. With each of his patients every small detail was gone into, and the most minute instructions were given, in fact usually written—an example which younger generations of medical men would do well to follow. In 1921 he took a partner with a view to retiring from practice, which he did in 1923. No man ever showed more loyalty to his partner or worked harder to further his successor's interests. He retired to live at Midhurst, and in retirement his unbounded energy, always devoted to his fellow men, found him on the Board of the Royal West Sussex Hospital, of which he became chairman 1929-30; and it was during this term of office that he had the honour of receiving the Princess Royal when she opened the David Ewart Memorial Nursing Home. In the same year he was made a J.P. for Sussex. He was a most enthusiastic St. Thomas's man, following all the hospital's activities so far as he could, frequently arriving there with patients—often in the middle of the night—and, when his work permitted, turning out to see the hospital play in the inter-hospital rugby matches. There were few gatherings connected with the hospital at which he was not to be seen. He was a keen member of St. Thomas's and Guy's United Hospital Club, and a regular attendant at all its dinners and lunches; in 1930 he took the chair at the St. Thomas's Old Students' annual dinner. At the end of the last war, when a fund was started as a memorial to old St. Thomas's men who had died for their country, he was instrumental in collecting a large part of the money, and served on the committee entrusted with its administration. His life was a great example in carrying out the ideals of the medical profession.

W. H. C. R.  
E. N. S. R.

Dr. LAURENCE JAMES BLANDFORD of Worcester died after a short illness on Feb. 29. He was born at Coxhoe, Durham, in 1876 son of Col. J. W. Blandford, and received his education at Repton School and Durham University. He graduated M.B., B.S. in 1899, and after a house-surgeoncy at the Royal Victoria Infirmary, Newcastle, proceeded to the M.D. in 1902, and some years later took the D.P.H. of the Dublin Royal Colleges, with honours. Dr. Blandford attained the rank of colonel A.M.S.(T.) in the last war, and was awarded the C.B.E. and Territorial Decoration in 1919 for his services with the 50th Division. After the war he became Deputy Commissioner for Medical Services under the Ministry of Pensions, and later Principal Medical Officer for the Midlands Region. He had been M.O.H. for Stockton-on-Tees Rural District and honorary surgeon to the Stockton and Thornaby Hospital. He joined the B.M.A. in 1900 and represented his Division at three Annual Meetings. He served at headquarters on the Naval and Military Committee, on the Territorial Force Committee, and on the committee concerned with expansion of Army Medical Services in case of national emergency.

Dr. PERCY JAMES KELLY died at Maidstone on Feb. 12 after a short illness, aged 68. He studied medicine at the University of Glasgow, and after qualifying M.B., Ch.B., joined the Colonial Medical Service in 1908. He served in Nigeria, Hong Kong, and Ceylon, where he was Registrar of the Medical College, and in British Guiana, where he was Surgeon-General from 1922 to 1932, in which year he retired and was awarded the C.B.E. During the last war Dr. Kelly was a captain in the R.A.M.C. at Salonika and in France; in 1936 he led the second Red Cross expedition to Abyssinia, which reached Gondar before it was compelled to retire by the victorious Italians. During the present war he served in several ships of the Merchant Navy which took part in the North African and other operations; he was about to sail again when his life was cut short. Dr. Kelly was president of the British Guiana Branch of the B.M.A. in 1927-8. He leaves a widow, two sons who are now serving with our Forces on the Burma Front, and two daughters. The elder son is Major L. M. Kelly, I.M.S.

The medical profession, general practitioners in particular (writer H. C. P.), are the poorer by the sudden and tragic passing of ARNOLD GEORGE TOLPUTT on Feb. 18. Of that truth ample evidence was provided by the gathering of every class of the community assembled at Kettering Parish Church on Feb. 21 to pay their last tribute of respect and affection to his memory. Every body, every organization, ambulance, fire brigade, wardens and A.R.P. personnel, police, town council, hospital staff, nursing and medical, those with whom he had spent so much of his time with untiring devotion, skill, and energy, in addition to a host of his patients and friends, were all there in token of their gratitude to Arnold Tolputt for his unfailing kindness and generous character. He came to Kettering well over 40 years ago as locumtenent with Dr. Paul Roughton, who was not slow to realize that he had discovered a man of outstanding ability and character. A firm and lasting friendship

## GLAXO PRODUCTS

PRODUCTS OF THE  
GLAXO LABORATORIES

● In time of war certain standard preparations are brought to your attention less frequently, due to lack of space, and sometimes because output is severely restricted; a few are listed below because we are often asked whether they can still be supplied. Some are in short supply but every effort is made to ensure fair distribution.

**BERIN. Aneurine Hydrochloride**

Preparations of a neurine base for oral and parenteral treatment of B<sub>1</sub> deficiency and of neural, vascular and gastro-intestinal manifestations. Tablets of 1 and 2 mg., ampoules of 5 and 25 mg.

Tablets: 25, 100 and 500  
Ampoules: 6, 12 and 50

**DEROBIN. Dithranol.**

2 to 5 times as active as chrysarobin. For the treatment of psoriasis and resistant parasitic and mycotic infections.

Tubes of 1 g. & 10 g.

**FERSOLATE. Ferrous Sulphate Tablets.**

Each contains ferrous sulphate (anhydrous) 3 gr., copper sulphate 1/25 gr. and manganese sulphate 1/25 gr. In hypochromic anaemia, 3 tablets daily produce optimum haemoglobin regeneration.

Bottles of 100 & 1000

**MERSAGEL.**

Phenyl mercuric acetate (1 in 750) in a cream base for the treatment of fungus skin infections including athlete's foot.

Jars: 1 1/2 oz. & 1 lb.

**OSTOMALT.**

Each fl. oz. contains 8,500 i.u. vitamin A, 2,000 i.u. vitamin D and malt extract 75 per cent. Ca glycerophosphate, 0.5 per cent., concentrated orange juice 1.3 per cent. Particularly acceptable to children for whom it is a valuable restorative tonic after illness.

Jars: 1 lb. & 1 lb.

**PREPALIN.**

High concentrates of vitamin A for intensive treatment. Capsules, 24,000 i.u.; Liquid, 72,000 i.u. per cc.; Ampoules, 100,000 i.u.

Capsules: 25, 100 & 1000. Liquid: 8 cc.  
Ampoules: 6 & 12

GLAXO LABORATORIES LTD., GREENFORD, MIDDLEX. BYRON 3434

# 'MIL-PAR'

Brand Regd.

## ANTACID LUBRICANT

A pleasant and effective combination of 'Milk of Magnesia' with a specially selected grade of Medicinal Paraffin. Particularly indicated in the treatment of chronic constipation and hyperacidity of the stomach due to disorder of the alimentary tract.

'MIL-PAR' neutralizes excess gastric acidity and checks the development of acid conditions in the food

waste. Mixing freely with the faecal mass it renders it soft and pliable and lubricates the intestinal tract without formation of oily pools and subsequent rectal leakage.

May freely be employed during convalescence from operation or protracted illness, for infants and children, expectant and nursing mothers.

Contains approximately 25% medicinal paraffin and 6% magnesium hydroxide.

SUPPLIES ARE LIMITED BUT SUFFICIENT STOCKS ARE AVAILABLE FOR DISCRIMINATE PRESCRIPTION

# PROPAMIDINE JELLY and CREAM

## for the prevention and treatment of sepsis

PROPAMIDINE is one of the aromatic diamidines, a series of compounds synthesised in the May & Baker Research Laboratories. Studied originally for their anti-protozoal action they were found to possess anti-bacterial properties which are not inhibited by pus and tissue fluids or para-aminobenzoic acid. Propamidine is active against sulphionamide-resistant strains of beta-haemolytic streptococci. For topical application in the treatment of infection, therefore propamidine possesses advantages over the sulphionamides of the same nature as are shown by penicillin.

Two preparations of propamidine are now freely available commercially, a jelly and a cream, each containing 0.15 per cent. w/w of 4: 4'-diamidinodiphenoxypropane di-(beta-hydroxyethanesulphonate). The first is used for established sepsis in wounds and burns as in the presence of sloughing or rough granulations more intimate contact of the drug with the infected area is secured. For other purposes the cream is employed and provides a valuable "first aid" application for burns.

A pamphlet on these products is available on request.

Propamidine Jelly is supplied in jars of 4 ozs. and 16 ozs., and the Cream in jars of 4 ozs.

## VIMALTOL

(VI-MALT-OL)

### *A Delicious Concentrated Vitamin Food*

TO the physician requiring a product which incorporates the important vitamins in a form entirely pleasant and acceptable to every patient, "Vimaltol" presents special advantages.

"Vimaltol" is a concentrated and economical vitamin food with a delicious orange flavour. The vitamins are supplied from specially prepared malt extract and yeast, which is one of the richest natural sources of vitamin B, together with Halibut Liver Oil fortified with additional vitamins.

"Vimaltol" is thus an important aid in the treatment of the many abnormal conditions resulting from the deficiency of one or more of the essential vitamins in the average every-

day dietary. The routine use of "Vimaltol" helps normal development of the growing organism and the maintenance of correct metabolism, while raising the general resistance against infection.

It is of signal value at certain physiological periods, such as infancy, adolescence, and pregnancy, to promote resistance to deficiency diseases and to assist in restoring normal metabolism in the many "borderline" cases arising from insufficient intake or defective assimilation of the essential food factors.

"Vimaltol" has thus a very wide application in general practice for patients of all ages. It can be prescribed with advantage at all seasons.

*A liberal supply for clinical trial sent free on request.*

and successful partnership were soon established. As I am proud to think, one of his oldest friends, I am as well qualified to express, though imperfectly, the appreciation of a colleague who was a man in the truest sense, a loyal friend, one who was honest and straightforward in his dealings with all men and a practitioner of marked ability and wide experience. I look back with pleasure on very many happy hours during the last 43 years spent in co-operation and friendly rivalry with him in our professional and social activities. To say that we shall miss him does not express all that we feel. It can be truly said of him, "Well done, thou good and faithful servant."

Dr. LYDIA ANN LENEY died in London on Feb. 15. The daughter of Edmund Lenev, she was born at Lewes, and from Cheltenham Ladies' College entered the London School of Medicine for Women. In 1895 she took the Scottish Triple diplomas and in the following year obtained the L.M. of the Rotunda Hospital and the M.D. of Brussels University. Her main professional interests were ophthalmology and instruction of mothers in the care of children. Dr. Lenev was for some time assistant R.M.O. at the Medical Mission Hospital, Plaistow, and then M.O. in charge of the Mary Ward School for Mothers. With this work she combined that of oculist under the old London School Board; later she became chief assistant at the Royal London Ophthalmic Hospital, refractionist to the L.C.C. Clinic, Battersea, and examiner and lecturer in first aid, home nursing, and infant care under the L.C.C. She joined the B.M.A. in 1898 and was a member of the Oxford Ophthalmological Congress and the West London Medico-Chirurgical Society.

Dr. ROBERT NIMMO WATSON died suddenly at his home in Harrogate on Feb. 15, aged 67. He was born at Invercargill, New Zealand, and studied medicine in London at the Westminster Hospital, where after qualifying M.R.C.S., L.R.C.P. in 1900 he held house appointments. He joined his cousin, the late Dr. Crawford Watson, at Harrogate in 1902 and became honorary physician to the Royal Bath Hospital and Rawson Convalescent Home; he also served for 40 years as medical officer to the Northern Police Convalescent Home and Orphanage. Dr. Watson joined the B.M.A. in 1903 and was a member of the International Society of Medical Hydrology. He had been president of the Leeds and West Riding Medico-Chirurgical Society and of the Harrogate Medical Society. During the last war he served over-seas with the rank of temporary captain, R.A.M.C.

We regret to announce the death on Feb. 21 of Dr. HERBERT HALL, who had a large practice at Hartlepool, and was senior honorary physician to the Hartlepool Hospital. He was born near Dublin in 1898, and graduated M.B., B.Ch., B.A.O. of Dublin University in 1922, after serving in the last war as surgeon probationer R.N. He became house-surgeon at the Hartlepool Hospital in 1924, and a year later, when he joined the late Dr. Brogden in partnership, he was appointed to the honorary staff, and also held the posts of district medical officer, public vaccinator, and police surgeon. In his private practice Dr. Hall won the affection of his patients and proved himself a good and kind friend to many poor families. He had a particularly warm regard for children, and did much to help young people in Hartlepool, as the probation officers and other welfare workers can testify. Dr. Hall joined the B.M.A. in 1925, and was elected chairman of the local Division in 1936.

Mr. WILLIAM MCGREGOR YOUNG of Leeds, who died last month, was educated at the University of Glasgow, taking first an Arts course and graduating M.A. in 1885. He then became a medical student and took the degrees of M.B., C.M. in 1889 with commendation, and proceeded M.D. in 1901. Throughout the whole of his medical career he practised in Leeds. He was for many years honorary surgeon to the Leeds Maternity Hospital and surgeon to the Leeds Southern Dispensary. He joined the B.M.A. in 1897 and had been an active member of the North of England Obstetric and Gynaecological Society and of the Leeds and West Riding Medico-Chirurgical Society. In former years he often acted as anaesthetist for the late Lord Moynihan, and he wrote the article on ether for the *Encyclopaedia of Medicine*. Long before 1914 he had been a keen Volunteer, and during the last war he was in command of the 2nd West Riding Field Ambulance with the rank of lieutenant-col. R.A.M.C.(T).

We regret to announce the death in retirement at Oulton Cross, Stone, Staffordshire, of Mr. REGINALD ALCOCK, C.B.E., F.R.C.S.Ed. He was born in 1868, son of John Alcock, J.P., of Portland House, Burslem, and was educated at Owens College, Manchester, where he won the Hulme Hall Scholarship. He graduated M.B., Ch.B. of the Victoria University in

1893 and took the F.R.C.S.Ed. diploma in 1910. He then returned to the Potteries and spent the rest of his life there, serving many years as surgeon to the North Staffs Royal Infirmary and consulting surgeon to the Leek Cottage Hospital and the Haywood Hospital, Burslem. During the last war he was senior surgeon to the Stoke-on-Trent War Hospital, and for that service was awarded the C.B.E. in 1919. Mr. Alcock joined the B.M.A. in 1894, had been honorary secretary of the North Staffs Division, and in 1922 president of the Staffordshire Branch; he was also a vice-president of the North Staffs Medical Society.

Dr. Muriel Barton Hall writes: May I add my regret to that of another correspondent at the passing of HERBERT NORT. He practised for many years not at Long Sutton, but at Little Sutton, where he was loved and respected by his patients. He brought my four younger sisters into the world, and I recall from an early age his dapper figure walking into the house unannounced, his confident, reassuring manner, the twinkle in his eye, and, as I grew up and became a medical student, evidence of his skill and efficiency. He was the perfect general practitioner to rich and poor alike, and his decision to give up his country practice in order to specialize was a grievous loss to his patients, many of whom still recall his services with admiration and gratitude.

## Medico-Legal

### SURVIVORSHIP IN AIR RAIDS

The succession to property sometimes depends on which of two or more persons involved in a common calamity dies before the others. Before the sweeping changes which Lord Birkenhead introduced into property legislation in 1925, the law assumed that "commorientes" died simultaneously unless evidence showed otherwise. The Law of Property Act, 1925, Section 184, provided that where two or more persons have died in circumstances which render it uncertain which of them survived the others, then the deaths are presumed to have occurred in order of seniority, the younger surviving the elder. In 1942 Mr. Justice Bennett tried the first case under this section arising from an air raid. A husband and wife were found dead after a bomb had fallen on the house where they were sleeping in the same room, but the judge held that their simultaneous death had to be positively proved by evidence, and he did not find the evidence brought in favour of it strong enough to override the presumption that the younger survived the elder.

This somewhat unsatisfactory result, though it seemed to accord with the wording of the statute, has now been modified by the Court of Appeal.<sup>1</sup> Five members of a household were killed together in a basement shelter by the same bomb. A brother of two of the victims, claiming as a residuary legatee of one and next of kin of the other, claimed that, as no proof was given that the victims had died together, they should be deemed to have died in order of seniority, which would have had the effect of invalidating wills made by some of the victims. The Master of the Rolls, Lord Greene, said that the first question was whether as a matter of law two persons can ever die simultaneously. Counsel had argued against the plaintiff that the law does not recognize this possibility because, as time is infinitely divisible, one of two persons must always in fact die before the other, though it is usually impossible to prove which died first. He described the infinite divisibility of time as a scientific fact, but Lord Greene preferred to call it a metaphysical conception. No doubt, his lordship added, when a bevy of angels is performing salutatory exercises on the point of a needle it is always possible to find room for one more. Propositions of this character appeared to him, however, to be ill suited for adoption by the law of this country, which proceeds on principles of practical common sense. To speak of the infinite divisibility of time in relation to a modern high-explosive bomb bursting among persons in a shelter seemed to him to ignore the realities of the case. He did not regard simultaneous death in these circumstances to be so improbable as some authorities, including Mr. Justice Bennett, had thought. Nor did he think that the words of the section covered the case of simultaneous death. He thought that the words "uncertain which of them survived the others" applied only to a case in which the proper inference from the facts is that the victims died consecutively; it does not, he said, apply if the court finds on the evidence that they died simultaneously. In such a case Parliament has not laid down a presumption about the order of death. To the present case the possibility of the deaths having been consecutive was too remote to be considered. He gave the warning, however, that simultaneous death need not be inferred in every case in which two persons are killed by the same bomb. Where, for example, two

<sup>1</sup> *Re Gressenior*, (1944) 1 All E.R. 81.

persons killed by blast were some distance away from one another, the court might well decline to draw the inference; and if the persons were killed by splinters the possibility that their deaths were simultaneous might be remote. Lord Justice Goddard agreed, but Lord Justice Luxmoore could not feel so certain as his brother judges that the victims had died simultaneously. He had heard of cases in which, when shelters had been hit, some of the inmates were found alive though the others had perished. The vagaries of burst and blast were notorious. He felt he would require the assistance and experience of an expert before he could conclude that two or more given persons died at precisely the same moment.

## The Services

Acting Surg. Cmdr. K. Forsyth has been awarded the R.N.V.R. Officers' Decoration.

The *London Gazette* has announced the appointment as O.B.E. (Military Division) of Capt. (Temp. Major) N. B. Hall, R.A.M.C., in recognition of gallant and distinguished services in the field.

### CASUALTIES IN THE MEDICAL SERVICES

*Wounded.*—Temp. Majors F. Elliott and A. A. C. Ross, R.A.M.C.; Lieut.-Cols. S. T. Davies and V. E. M. Lee, I.M.S.

*Prisoners of war.*—Temp. Majors P. M. Bloom and E. Egan, Capt. C. Hecht, War Subs. Capts. J. F. Clark, H. E. De Warden, J. Diver, R. W. Lennon, J. C. McNeilly, and J. E. Moss, and Lieut. P. T. Chopping, R.A.M.C.; Temp. Lieut.-Col. G. B. S. Chawla, Major K. Rai, Acting Majors S. A. Hasan and K. N. Rao, and Capt. N. G. Latey, I.M.S.

*Missing at sea.*—Capt. J. R. O. Thompson, R.A.M.C.

*Missing, believed killed.*—Surg. Lieut. D. L. Sandes, R.N.V.R.

*Died.*—Major S. W. H. Askari, I.M.S.

### DEATHS IN THE SERVICES

Air Commodore BASIL ALFRED PAYNE, D.S.O., who retired from the Medical Branch of the R.A.F. in 1938, died on Feb. 6 after a long illness at Minchinhampton, Gloucestershire. He was born in 1885 youngest son of the late Edward Payne of Minchinhampton, and from Clifton College entered Pembroke College, Cambridge, with an exhibition, taking his B.A. in 1907. He then went on to St. Bartholomew's Hospital, and qualified M.R.C.S., L.R.C.P. in 1910. After serving as extern midwifery assistant at Bart's and senior house-surgeon at the Miller General Hospital, Greenwich, he graduated M.B., B.Ch. at Cambridge in 1912. For his services as a temporary surgeon R.N. throughout the last war he was mentioned in dispatches and awarded the D.S.O. in 1915. Joining the R.A.F. he held a number of posts and became Principal Medical Officer in turn of the Aden Command, the Iraq Command, the Halton Command, and from 1934 until his retirement in 1938 of Coastal Command Headquarters.

## Universities and Colleges

### UNIVERSITY OF CAMBRIDGE

A Congregation held on Feb. 25 the following medical and surgical degrees were conferred:

M.Chir.—B. N. Brooke (in person).

M.B., B.Chir.—R. C. Barclay, K. Chitty, F. A. L. da Cunha (all by proxy).

### UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—IP S. London, P. Abbey, A. C. Akehurst, Winifred N. Backhouse, G. H. Bancroft-Livingston, Winifred M. Bond, W. Brand, Elizabeth T. Brash, P. Brightwell, F. S. W. Brimblecombe, H. W. Bunle, G. E. Catton, E. H. Couper, W. E. Craddock, Catherine F. Crofts, A. J. E. Duddington, P. D. A. Durham, W. H. Dyson, A. J. Eley, M. E. Evans, J. M. Fabricius, Elizabeth de C. Falle, D. L. B. Farley, S. C. Farman, J. H. Ferris, P. G. Finch, C. O. Fung-Kee-Fung, G. W. Garland, A. P. Goffe, M. E. I. Halford, L. H. Hamlyn, R. H. Heptinstall, E. G. Herzog, A. J. H. Hewer, Norah Hewison, Monica M. Hogben, J. E. Hotchin, C. A. Houlder, Elizabeth M. Hugill, R. W. L. Hurt, P. E. Jackson, B. V. Jones, E. C. B. S. Keat, Margaret Kemsley, A. B. Lee, C. A. Leeson, M. Leivers, E. Levy, W. D. Linsell, G. R. G. Mackarness, K. M. Mackenzie, T. P. Mann, C. G. Martin, L. G. C. Martin, Edith S. M. Merry, J. K. Morgan, W. S. Morgan, D. Munro-Ashman, Jean Myers, Diana J. Myott, A. Noskwith, A. W. Nurick, A. C. F. Oakley, J. P. Partridge, Cicely Penler, Marion J. Phillips, J. E. L. Price, L. Radcliffe, A. M. Rajah, D. L. Rees, T. H. Richards, D. R. S. Saunders, J. Siegler, I. R. Sinton, I. T. The, A. M. B. Tompkin, E. L. Trickey, G. Trosier, Joyce F. Tucker, E. Tuckman, K. A. D. Turk, E. C. Turner, Eileen M. Vale, R. G. White.

(With honours and distinction in surgery.)

### UNIVERSITY COLLEGE HOSPITAL

Prof. A. A. Miles, F.R.C.P., will deliver the Sydney Ringer Memorial Lecture for 1944 in the lecture theatre of University College Hospital Medical School, University Street, Gower Street, W.C., on Tuesday, March 21, at 4 p.m. His subject is "The Epidemiology of Wound Infection," and the lecture is open to qualified practitioners and medical students.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following lectures, open to medical practitioners and advanced students, will be delivered this month at the College in Lincoln's Inn Fields at 4 p.m. One Hunterian Lecture by Prof. L. Leigh Collis on March 14 on the aetiology of cerebral abscess as a complication of thoracic disease; two lectures by Dr. Geoffrey H. Bourne, on March 21 on the problem of bone formation, and on March 23 on vitamin C and the regeneration of bone; two lectures by Prof. Arnold Sorsby, on March 28 on blindness in childhood, past achievements and present problems, and on March 30 on the sulphonamides in ophthalmology, their use and limitations.

*Correction.*—Owing to a printer's error in the report of the meeting of the Royal College of Physicians of London in the *Journal* of Feb. 12 (p. 239) the following names were omitted from the list of candidates who had passed the Final Examinations of the Conjoint Board:

W. R. Horstall, C. A. Houlder, Elizabeth M. Hugill, A. L. Humphrey. The initials of T. M. Humphry were wrongly given as W. R. Humphry.

## Medical News

Two organizations—the Health Workers' Council and the Social Security League—have jointly arranged a public conference on "Planning for Health: Medical Services and the Beveridge Report," to be held in the Conway Hall, Red Lion Square, W.C., to-morrow (Sunday, March 12) from 3 to 6.30 p.m. The speakers will include Dr. Haden Guest, M.P., and Dr. H. Joles.

A meeting of the Clinical Society of the Royal Eye Hospital will be held at the hospital on Friday, March 17, at 4.30 p.m., when a talk will be given by Mr. L. V. Cargill on "Sir William Bowman."

At a meeting of the Tuberculosis Association to be held at Manson House, 26, Portland Place, W., on Friday, March 17, at 3.15 p.m. a discussion on the problem of primary tuberculosis in children, especially in the under-5 age group, will be opened by Drs. W. Gaisford, W. Richards, A. Margaret Macpherson, and G. Jessel. Members of the British Paediatric Association have been invited to take part in this joint discussion.

Dr. Innes H. Pearce will give a public lecture on "The Peckham Experiment" on Wednesday, March 22, at 6.45 p.m. in the Alliance Hall, Palmer Street, Westminster, S.W. Applications for seats to be reserved should be sent to the Secretary, Science (Research) Society, 31, Broadhurst Gardens, Eastcote, Middlesex.

The London School of Hygiene and Tropical Medicine has arranged a week-end course for medical practitioners on Factory Medical Services and Industrial Diseases on Saturday and Sunday, March 25 and 26. The session on March 25 will be opened at 2 p.m. by Sir Wilson Jameson and will be devoted to tuberculosis and the industrial worker and to industrial diseases of coal-miners. At the morning session on March 26 medical inspection of canteens and young persons in industry will be discussed, and in the afternoon a paper on medical selection of factory personnel will be followed by a medical "brains trust." The fee of one guinea for the course (and 2s. 6d. if lunch is required on Sunday) should be sent to the Secretary of the School, Keppel Street, W.C.1, not later than March 20.

It was announced in 1941 that since large quantities of phenol were required for purposes directly connected with the war, its use for other purposes should be restricted as much as possible. We understand that the supply position has improved, and that increased quantities are now being made available for medical use.

At a meeting of the Central Midwives Board for Scotland, Prof. R. W. Johnstone, P.R.C.S.Ed., and Prof. James Hendry were elected Chairman and Deputy Chairman respectively for the ensuing year. Examiners were appointed and institutions were approved for the training of pupil midwives.

By an amendment, which became official on Feb. 18, a monograph on liquid extract of belladonna leaf has been added to the *British Pharmacopoeia*, 1932. In future when liquid extract of belladonna is prescribed or demanded, liquid extract of belladonna leaf may be dispensed or supplied.

The supply of rubber gloves to hospitals and similar institutions, and through them to doctors, nurses, and midwives for use in institutions will continue to be controlled centrally by the Priority Officer of the Ministry of Health as at present. For doctors in private practice the ration will be six pairs a year, and applications for certificates should be made to the Central Medical War Committee, B.M.A. House, Tavistock Square, W.C.1, marking the envelope "Gloves" and enclosing a stamped addressed envelope for reply. Applications for "supplementary rations" should be made to the Regional Offices of the Ministry of Health.

The December issue of the *Medical Record* of New York is a Neuburger number devoted to Prof. Max Neuburger, the eminent medical historian, in celebration of his 75th birthday.

The Marcel Benoist prize for 1943 has been awarded to Prof. Arthur Stoll of Basle for his work on pharmacological chemistry.

Dr. H. G. Massiah has been appointed a member of the Legislative Council of the Island of Barbados.

## EPIDEMIOLOGICAL NOTES

### Discussion of Table

In *England and Wales* during the week there were rises in the incidence of measles by 375, scarlet fever by 193, acute pneumonia by 65, and of dysentery by 57 cases; the notifications of whooping-cough fell by 184. The deaths from influenza in the great towns have steadily dropped since the week ending Dec. 11, when 1,148 were recorded; there were only 38 deaths during the week under review; but the returns for the week ending Feb. 26 show an increase of 8 deaths.

There was an increase in the incidence of scarlet fever in most areas, the largest being in Warwickshire, with 34 more cases. Notifications of whooping-cough were down by 51, 49, and 38 in Yorks West Riding, Lancashire, and Sussex respectively, and up by 25 in London and 24 in Middlesex. During the past six weeks the incidence of measles has been trebled; the largest increases during the week were in Kent by 91, in Norfolk by 89, and in Lancashire by 87.

Dysentery, with 277 notifications, was again on the increase, the returns being the highest for any week during recent years except for two occasions in 1943. The only fresh outbreak of any size during the week was in Shropshire, Ludlow R.D. 26. The cases rose from 31 to 61 in London and involved seventeen boroughs (Hackney 23, Islington 11). The largest of the other centres of infection were Surrey 24, Glamorganshire 21 (Cardiff C.B. 20), Lancashire 16, Middlesex 13, Warwickshire 10.

In *Scotland* cerebrospinal fever and dysentery rose in incidence by 16 and 63 cases respectively, the notifications of these diseases being the highest during recent months. Half the 33 cases of cerebrospinal fever were reported from the city of Glasgow. The principal outbreaks of dysentery were Ayr county 61, Glasgow 20, Aberdeen county 10. There was a slight rise in the notifications of scarlet fever by 15 cases, and there were 35 fewer cases of whooping-cough, 26 of acute primary pneumonia, and 10 of measles.

In *Eire* there was a further small rise, 10, in the notifications of diphtheria. Of the 324 cases of measles 295 were notified in Dublin C.B.

### Smallpox: A Warning

Smallpox has appeared in the county of Middlesex, at Mount Vernon Hospital, where 3 out of 8 patients with the disease have died. A number of people have visited the hospital, and as many as possible have been traced and offered vaccination or re-vaccination. Practitioners are urged to be on the look-out for cases, and to seek advice from the regional or central medical staff of the Ministry of Health and the L.C.C. if in any doubt as to the nature of an eruption.

### Week Ending February 26

The returns of infectious diseases during the week in *England and Wales* included: scarlet fever 1,948, whooping-cough 1,810, diphtheria 690, measles 1,796, acute pneumonia 858, cerebrospinal fever 75, dysentery 234, paratyphoid 6, typhoid 7. The deaths from influenza in the great towns numbered 46, an increase of 8 on the total of the preceding week.

### Points from Abroad

According to a statement in the Swedish press last month Berlin is suffering from a plague of rats because refuse has not been removed for months. There is fear of contagious diseases, and hundreds of cases of tularaemia have already occurred in Berlin, although there had not been a single case for decades.

Last month about 5,000 cases of plague were reported in Adrianople, and quarantine restrictions were placed by Turkey on those crossing the Bulgarian frontier.

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 19.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

## Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Attilology Westcent*, London; SECRETARY, *Medisecra Westcent*, London. ADVERTISEMENTS, *Articulate Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

### ANY QUESTIONS?

#### The Carotid Sinus and Carotid Body

**Q.**—What are the physiological functions of the carotid sinus and carotid body, and what is their clinical significance?

**A.**—The carotid sinus and carotid body are concerned with the reflex regulation of arterial blood pressure, heart rate, and respiration. Nerve endings—stretch receptors—in the adventitia of the carotid sinus are responsive, as are similar endings in the arch of the aorta, to changes in arterial blood pressure. They are stimulated according to the pressure exerted on the walls of the vessels; when they are stretched impulses pass, in the case of the carotid sinus, via the sinus nerve to the vasomotor centre and inhibit its tonic activity. As a result an increase in pressure in the sinus is followed by widespread vasodilatation. Reflex slowing of the heart and of breathing is also induced through the cardiac and respiratory centres by an increase in sinus pressure. The usual constancy of the arterial blood pressure is attained mainly by reflex action induced through the sinus and aortic nerves—the two nerves are indeed often referred to as "buffer" nerves.

Associated with the sinus is the carotid body containing chemoreceptors which are stimulated by blood- $\text{CO}_2$ , tension rising above, and  $\text{O}_2$  tension falling below, threshold levels. Stimulation of the receptors results, reflexly, in increase in vasomotor centre tone and stimulation of breathing. The aortic bodies react similarly. The removal of  $\text{CO}_2$  and the maintenance of its optimum level and the supply of oxygen to the organism are therefore important functions of the carotid body. For details and experimental proof regarding these mechanisms the questioner is referred to Wright (*Applied Physiology*, 7th edition).

Clinically the sinus (and aortic arch) receptors are largely responsible for the maintenance and regulation of arterial blood pressure. Experimentally, hypertension can be induced in animals by section of the sino-aortic nerves, but there is little evidence that essential hypertension in man is due to dysfunction of the sinus mechanisms. Hypersensitivity of the carotid sinus reflex may be responsible for some forms of vasovagal fainting attacks. Subjects of this condition are characterized by the abnormal slowing of the heart which ensues from light or moderate pressure exerted on the neck over the carotid sinus region.

#### Bilateral Recurrent Parotitis

**Q.**—A patient aged 37, a Sino-Portuguese by birth, was born in Macao and has spent many years of her life in India. She has complained for the last three months of an intermittent swelling and pain at the angles of her jaw. On examination I have found that both parotid glands have been swollen, the right more so than the left. The swelling subsides so rapidly that on the day after I saw her the surgeon to whom I took her could find no swellings. There are no stones in the parotid duct, and there is no inflammation visible at the mouth of either duct. Can you suggest (a) the cause of this chronic parotitis, or (b) any investigations which might be made and which might throw further light on the complaint? I do not think for a moment that she has a mixed parotid tumour.

**A.**—The case is almost certainly one of bilateral recurrent parotitis. Bacteriologically, the majority of such cases are caused by the *Str. viridans*, with smaller groups caused by pneumococci, etc. The parotid secretion in such cases becomes turbid, and from time to time the ducts are blocked by small blobs of muco-pus and epithelial cells. A few of the cases, particularly those in which the parotid swellings appear and disappear very rapidly, have been considered as possibly allergic in origin, but a bacterial infection is usually present. Between the attacks the anterior border of the parotid is often much more easily palpable over the masseter muscle than in normal patients. The most useful investigation is the

catheterization of the parotid duct, preferably whilst the gland is swollen. For this a fine glass cannula and bulb are necessary. In the typical *Str. viridans* cases the saliva is turbid due to large numbers of minute blobs of muco-pus. Direct examination of these blobs shows pus cells and columnar and pavement epithelial cells, often with intracellular organisms. In pneumococcal cases the saliva is usually more uniformly turbid. Cultures should also be made of fluid obtained by catheterization. Further information may also be gained by taking a sialogram after the injection of lipiodol into the duct system. In the individual case treatment must be based on the information obtained from these investigations. Suppurative complications do not occur in the *Str. viridans* group, but subacute and loculated abscesses may develop in connexion with pneumococcal infection.

#### Registration of Maternity Homes

**Q.**—A widow, having some experience of maternity but no qualifications, and a spare room in a well-equipped and well-run house, has for the last two years been taking in maternity cases, mainly the wives of absent soldiers who have difficulty in finding domestic help to enable them to have their babies at home. Confinements, ante-natal and after-care have been carried out by a district midwife and doctor. She has now been informed by a representative of the county medical officer that she may not continue to do this as hers is not registered as a nursing home, and cannot be so registered without a resident qualified midwife. She is, however, at liberty to go to the homes of mothers to look after the domestic side of confinements. This she cannot do, as she has some family of her own to look after. I shall be glad of an opinion on the legal side of this problem.

**A.**—The lady has obviously been keeping a nursing home within the meaning of the Public Health Act, 1936, ss. 187-95. A nursing home includes a maternity home, which means any premises used or intended to be used for the reception of pregnant women or of women immediately after childbirth. The Act makes the M.O.H. of the county or county borough primarily responsible for seeing that the nursing homes of his area comply with its provisions. The control of such activities as the question describes may seem vexatious in such a case, but it is clearly necessary in order to check wholesale abuses such as baby-farming and criminal abortion. A nursing home is therefore illegal unless it is registered with the local authority, who may refuse registration for various reasons, among which is failure to provide a properly qualified superintendent and staff. Section 187 lays down explicitly that the nursing in a maternity home must be superintended by a qualified nurse or a certified midwife. On the other hand, although the Act says that a nursing home other than a maternity home must have a resident medical practitioner or qualified nurse, it does not impose this requirement on maternity homes. If, therefore, the sole objection of the local authority to registering this lady's house is that she has no resident qualified midwife, the authority appears to be exceeding the powers of refusal given it by the Act. Her proper procedure, if she cannot get the M.O.H. to agree with this view of the law, is to apply for registration. If the authority desires to refuse, it must give her a clear fortnight's notice in writing, with its grounds of refusal. If then she writes within a fortnight and asks for an opportunity for showing cause against the refusal, the council must give her one. If it then refuses, she is entitled to a free copy of the order, and she may appeal against it to a court of summary jurisdiction—the local bench of magistrates. The order must inform her of this right. If the bench takes the view that the council is exceeding its powers, it may order the council to license her. She should not admit any more mothers until she obtains her licence.

#### What is a Vaccine?

**Q.**—(1) What is a vaccine? (2) What is a non-bacterial vaccine? Does a mixed inhalant solution composed of dusts and pollens, etc., and used in desensitizing an asthmatic come under the latter category?

**A.**—By derivation the word vaccine means something obtained from a calf, and for many years vaccination meant nothing else than the process of immunization against smallpox by inoculation with the virus of vaccinia obtained from lesions in that animal. With the advent of other methods of immunization the same terms were also unfortunately used for other materials and proceedings, and a definition of the word vaccine which would be generally accepted now is "a suspension of killed or attenuated micro-organisms used for immunization." Whether the meaning of the term should be extended still further to embrace agents of non-microbic origin used for purposes of immunization or desensitization is perhaps a matter of opinion, but respect for the long-accepted meanings of words condemns such usage, and the answer to the first clause of the second question is that there is no such thing. A pollen extract remains a pollen extract whatever may be done with it, and there is no good scientific reason for calling it anything else. If a general term is wanted to cover agents of this nature, another much-abused word, "antigen," may correctly be applied to them.

## Flatulence and Fluids

**Q.**—In the case of cardiac affections we are taught that high solids form the best diet because fluid food is likely to cause flatulence. This would seem to exclude soups. Upon what physiological or pathological grounds do we base our view that fluid foods—e.g., soups—cause flatulence? If soups cause flatulence, is it osmotic flatulence or intestinal flatulence?

**A.**—There is not the slightest evidence to support the tradition that fluids cause either gastric or intestinal flatulence. The excess of gas present in the alimentary tract in heart failure, cirrhosis of the liver, and chronic bronchitis is caused by deficient absorption the result of venous congestion. Possibly some gas even passes from the blood into the lumen of the stomach and intestines. Dietetic restrictions have little effect, but it is worth while reducing the intakes of potatoes, other root vegetables, and rice, though this does not lead to anything approaching the relief it gives to the colonic distension of intestinal carbohydrate dyspepsia. Diastatic ferments are useless; a tablespoonful of powdered charcoal taken twice a day may help a little; but the only effective treatment is relief of the venous congestion by treatment of the primary condition. If the flatulent distension causes pain and the patient is constipated, complete evacuation of both faeces and gas from the colon can be obtained within a few minutes by the injection of 1-2 c.c.m. or less of pitresin if this is not contraindicated by the condition of the heart.

## Unexplained Exhaustion in Women

**Q.**—A few of my women patients, though not anaemic, have a poor reserve of strength. Their diet and environment are satisfactory, and they have never had serious disease, yet a small walk exhausts them, and they are as tired on waking as on bedtime. Physical examination gives no clue.

**A.**—Cases of this kind are not uncommon and they tend to be treated for intestinal toxæmia, focal sepsis, hormone deficiency, or avitaminosis according to the prevailing fashion or the date of graduation of the therapist. The tendency nowadays is to regard them as cases of depression, but the early onset, the trivial psychological strain, the absence of remissions, and the small success of psychotherapy make this explanation a little doubtful. Nevertheless encouragement and an interesting occupation are important elements of treatment. Small doses of benzedrine (amphetamine), 5 mg. at breakfast and midday, may also be tried.

## Gold Treatment of Rheumatoid Arthritis

**Q.**—A woman aged 54 years had rheumatic fever with endocarditis 20 years ago and made a good recovery. In the past 10 years she has developed rheumatoid arthritis, especially in the interphalangeal joints of the fingers, and there is definite rheumatoid arthritis of the knees. Would "gold" treatment of this condition be beneficial, and in what doses and how would I administer it? The pain is not excessive, but the condition is progressive and threatens to be crippling.

**A.**—It is not uncommon to meet with a history of rheumatic fever in earlier life in cases of rheumatoid arthritis. In the case under consideration gold would appear to be well worthy of a trial, but a warning is necessary against its use without previous experience as the risks are real, and sometimes, in spite of close observation, unfavourable effects arise. A thorough blood investigation should be carried out for anaemia and sedimentation rate; the former, if present, will call for attention first, possibly by administering liver at the same time as the gold is given, and iron in any case. It is wise to begin with a dose of 0.01 g. if myocristin is the preparation selected, and to increase gradually to 0.05, giving this at weekly intervals up to a total not exceeding 1 g. A careful watch for any signs of irritation of the skin or soreness of the mouth must be kept; the urine should be examined at frequent intervals and blood counts carried out; any decrease in the white cells may be a danger sign, and a lowered platelet count may be warning of possible haemorrhages, though these are one of the rarer complications. The wisest plan is for the patient to have the earlier stages of the treatment carried out in hospital or wherever skilled observation may be available. The method is fully described in the more recently published books on arthritis.

## Solphonamides and Rheumatic Fever

**Q.**—I understand that sulphonamides have been used in the prophylaxis of rheumatic fever. Could they be used in the treatment of subacute rheumatic fever, and if so, in what dose, say, should sulphanilamide be given and over how long a period?

**A.**—Sulphanilamide has been used during the winter months to prevent recurrent attacks of rheumatic fever. It is difficult to see how its value in this respect can be assessed under a period of many years. If it is effective it probably owes its efficacy to the prevention of the streptococcal tonsillitis which often precedes the reactivation

of the agent responsible for rheumatic fever. There is no evidence that sulphonamides are of value in the treatment of subacute rheumatic fever.

## Mercurial Poisoning

**Q.**—Is there any likelihood of mercurial poisoning from prolonged use of mersalyl or salyrgan? A patient aged about 56 has a high systolic blood pressure and failing right ventricle, with consequent dropsy and oliguria. He has been having daily doses of 2 c.c.m. for some time.

**A.**—Mercurial poisoning is very unlikely to result from the prolonged use of mersalyl or salyrgan. Thus a case was recorded in this Journal by C. M. McIntyre (1943, 2, 609) in which 680 injections had been given over a period of about 6 years with only occasional slight reactions which could be ascribed to mercury. Mercurial reactions, however, may occur. N. M. Keith (*J. Amer. med. Ass.*, 1936, 107, 2047) says: "The distressing reactions that have actually been seen after the injection of organic mercury are stomatitis, diffuse dermatitis, diarrhoea, haematuria, and renal insufficiency. Luckily, these reactions are rare." It is a wise precaution to see that there is no oral sepsis in any case in which prolonged administration is contemplated. Cramps may occur in the legs due to deprivation of sodium chloride, and these are relieved by adding salt to the diet. In other cases the patient complains of feeling ill and tired after the injections. This is probably due to excessive dehydration, and disappears when the injections are given less often. In the case referred to here it might be advisable to try giving the injections at five-day intervals, judging the effect by the excretion of urine and weight of the patient. If this is not successful the administration of ammonium chloride by mouth, in doses of 30 grains four times a day for three days before the injection and on the day of the injection, may give satisfactory results with only one injection a week. Sudden toxic reactions are rare. They include such symptoms as headache, unconsciousness, and epileptiform convulsions, as was reported by C. T. Andrews in this Journal (1942, 1, 24) in a case of heart failure in which kidney disease was excluded.

## INCOME TAX

## Cost of Air-raid Shelter

"Jay" expended £80 in building and equipping an air-raid shelter attached to the surgery of an industrial practice. He is informed that no allowance can be made on that account for income-tax purposes as the shelter was erected in connexion with a professional and not a "trade" concern.

\* That is correct. The underlying reason is that the special arrangements made to encourage the erection of shelters were intended for the benefit of employees, and therefore apply to factories, mines, and buildings used for commercial purposes, but not where the premises are put to professional use.

## Pension from Abroad

C. M., who is now residing and practising in this country, is in receipt of a small pension derived from service abroad with a foreign shipping concern. Is he liable to pay British tax on the pension?

\* Yes; British residents are liable in respect of such incomes even though earned by foreign service.

## "Pay as you Earn"

## Earnings Assessed under Schedule D

M. Ls.' husband is a specialist; for the past eighteen months she has been assisting in a general practice, and her earnings have been included, for income-tax assessment, in one sum with those of her husband. Can she claim to come under the new system?

\* "Pay as you earn" applies only to earnings assessed under Schedule E. M. Ls.' earnings should not strictly have been assessed under Schedule D, because she is in employment and is not in general practice. The only way in which the benefit of cancellation of 7/12ths of the 1943-4 tax can be obtained is for M. L. to arrange with the inspector of taxes for the Schedule D assessment on her husband to be reduced by the exclusion of her earnings, and for Schedule E assessment to be made on them specifically.

## Salaries paid to Partners

W. W. inquires whether there is any method by which a partnership may take advantage of this new system as regards "salaries" paid to partners.

\* No. The Income Tax Acts regard payment of such "salaries" as really an arrangement for the distribution of profits between the partners. The "salaries" are not deductible in arriving at the amount of the Schedule D assessment, are not assessable under Schedule E, and accordingly do not come within the new "pay-as-you-earn" system.

## LETTERS, NOTES, ETC.

## Thiouracil: A Warning

Dr. DAVID HALER (London, W.1) writes: In your reply to a question on the above subject (Feb. 26, p. 313) you state that no other toxic effects apart from a skin rash have been described. This is not a fact. Thiouracil is a dangerous drug, and at least half a dozen fatal cases of agranulocytosis have been described following its use, and only this week I conducted a necropsy upon such a case, the inquest resulting in a verdict of misadventure following the administration of thiouracil. In my opinion this drug should be given only under the strictest in-patient control, when full pathological and clinical facilities are available for full control of the case. I feel it to be of sufficient importance for you to give this warning adequate publicity.

## Ephedrine and Argylol in Normal Saline

Messrs. E. W. BASTOW and T. D. WHITET (pharmacists, Charing Cross Hospital) write: Following the letter of Dr. A. Piney (Jan. 29, p. 163), we have prepared solutions containing ephedrine and argylol in normal saline without any difficulty, and we are surprised there has been trouble in the preparation of a satisfactory solution. A solution made with argylol (Barnes) is indistinguishable from the proprietary article, and shows no precipitate after over a week, being bright and clear. A second solution prepared with argent. vitellin B.P.C. also appears quite stable after several days, and although not quite so bright as the first solution, it has no sign of a precipitate. The most satisfactory method of preparation is as follows. Dissolve the amount of argylol in about half of the water required and the salt and ephedrine hydrochloride in another portion, mix the two solutions, and dilute to volume. The finished solution should be stored in a dark bottle. It is proposed to investigate this matter further, and submit a short paper to the *Pharmaceutical Journal*.

## Paul-Bunnell Test

Dr. F. DURAN-JORDA (Manchester) writes: I notice that in the *Journal* of Dec. 11 (p. 771) there is a reply to a question concerning the Paul-Bunnell test for infectious mononucleosis. In the first paragraph of the reply there is a short description of the method, in which the reader is given to understand that by mixing the serum with a 2% suspension of sheep blood cells an agglutination is produced in small dilutions in any kind of serum, normal or abnormal. I have not seen any further correspondence on this subject which may have rectified the description, but I should like to point out that the serum should first be inactivated, because the mixing of fresh human serum with sheep blood cells produces haemolysis instead of agglutination, due to the fact that in the human serum there is normally an antihæmolytic factor against the sheep cells which acts when the normal-serum content of the complement has not been destroyed by heating.

## Structure of Atropine

Dr. J. N. DAVIDSON and Dr. I. C. WHITFIELD (Aberdeen University) write: The similarity between pethidine and atropine as indicated in the paper by Drs. Gallen and Prescott (Feb. 5, p. 176) would be less marked if the structure of atropine were correctly presented. The formula shown is an ester of a tropane carboxylic acid, whereas atropine is, of course, the *dl*-tropic acid ester of tropine.

## Photomicrography with Ordinary Cameras

Mr O. L. WADE writes from Cardiff: I read with interest the article on this subject. Some of your readers might be interested to know that very effective cine-photos of microscopical preparations can quite easily be taken. In pre-war days I made a successful film of hydra and daphnia and other small pond life using a  $\times 6$  eyepiece and a 1/6-in. and a 1/3-in. objective. The light was a carbon arc lamp run off the house mains. The microscope tube was placed horizontally on a specially made holder. The preparation was clipped to the microscope stage, and to protect it from the heat of the lamp the light was passed through a glass jar of copper sulphate solution. The camera, in this case a 9-mm. Pathé, was applied to the eyepiece of the microscope: its casing was opened and the microscope focus adjusted until a sharp image fell on a piece of cardboard placed where the film lies during exposure. A little experimentation, exposing and developing only small sections of film, enables the optimum conditions to be found. We suffered great difficulty as we did not possess a two-way prism eyepiece, and were unable to view the field while exposing film. To ensure that the animals did not pass out of the microscope field we made a small cell 1 cm. by 1 cm. by 1/10 cm. on a microscope slide and pushed in a few strands of cotton-wool. This divided up the cell into small compartments and prevented the animals swimming outside the microscope field. The difficulty with very high-power work, 1/6 in. or 1/12 in., is to make the living cells show up against the bright light. I am hoping to have success in photographing phagocytic cells stained by Maximow's supravital stains (Sabin, Doan, and

Cunningham, *Contributions to Embryology*, 1925, Nos. 82, 83, 84). I think it would also be possible to photograph living preparations as made by Covell (*Anatomical Record*, 1928, 40), where the cells are excreting granules stained by dyestuffs injected intravenously.

## Pin-hole Urinary Meatus

Mr. FAUSET WELSH, F.R.C.S. (Birmingham), writes: In your issue of Feb. 26 (p. 314) a questioner describes under the term "pin-hole meatus" a condition which I recognize as meatal ulcer. The answer given does not satisfy me, nor will it satisfy anybody who has to treat this troublesome little complaint. In the first place there is little doubt that the pin-hole meatus is caused by the meatal ulcer and not vice versa. The smallest meatus which we ever see in a child is the one found in hypospadias, but we never see spontaneous ulceration here. Again, ulceration of the meatus is not found in the uncircumcised child. It is very common after circumcision, though an interval of three months to eighteen months may elapse between the operation and the onset of ulcer symptoms. Lack of the protection normally given by the prepuce is responsible for ulceration at the lips of the meatus. Friction by the clothing or ammoniacal dermatitis are probably the other factors setting up the ulcer. A scab forms across the meatus and the child can urinate only by bursting this scab, a process accompanied by pain and the appearance of a few spots of bright blood. The scab then re-forms and the process is repeated. The ulcer will heal if, after micturition, a small square of lint smeared with a blob of medicament, such as ung. H.A.D., is placed over the meatus. Healing is sometimes accompanied by stenosis, and if the meatus is unusually small a meatotomy will be required. This is a very delicate operation.

## Abdominal Injury and Intussusception

Mr. A. S. ALDIS, F.R.C.S. (senior assistant, Surgical Unit, Welsh National School of Medicine, the Royal Infirmary, Cardiff) writes: May I have the hospitality of your columns to seek information in connexion with a somewhat unusual case which has just come under our care? The patient is a boy aged 9 who was run over by a milk van, the wheel passing across his abdomen. There was little external sign of injury and the boy's condition was so good, with no abdominal rigidity, that operation was deferred. Twelve hours later the patient started to vomit and there was some visible peristalsis in the upper abdomen together with tenderness and a rising pulse rate. A laparotomy was performed and the boy was found to have a small rupture of the liver and some bruising of the pancreas. In a routine investigation of the other viscera he was also found to have an entero-enteric intussusception about three inches long near the junction of the jejunum and ileum. The small intestine above the intussusception was dilated, and below was it spasm. No other injury was found in the abdomen, the intussusception was easily reduced, and no abnormality of the bowel or hæmatoma of its wall was discovered to account for its occurrence. I would be most interested to know whether any readers have seen a similar association of abdominal injury and intussusception. It seems to me to be a true example of enterospasm initiating an intussusception.

## Rare Medical Books

Dr. M. G. BASTABLE (Stranraer, Co. Donegal) writes: Under the heading "Rare Medical Books" (Jan. 22, p. 138) you mention some rarities now to be sold, among them being Moore's *Hope of Health* (London, 1564) and other similar manuscripts. Some of your readers may be interested to know that the Government Publication Department in this country has a team of scholars working on unpublished Irish texts, some of which have already been reprinted at a very moderate price. The most recent of these is the *Regimen Sanitatis Magistri Mediolanensis*, containing both the Latin version and the Gaelic translation. In a scholarly introduction (in English) the editor says: "The large body of mediæval Latin medical work has generally an interest only for the specialist in the history of medicine, while early translations of such texts into the several European vernaculars have mainly interested lexicographers. If this fourteenth century *Regimen Sanitatis* of Maginus, a doctor of Milan, were to make further claim it would be on the student of the social history of the period; a rule for the preservation of health; it has necessarily a broader compass than works on the treatment of specific disease or conditions. . . . Early translations of such texts into the vernacular may be of importance in establishing a critical Latin text, and in this connexion it might be noted that the earlier of the two extant Irish MSS. of the *Regimen* (P, dated 1469), though not the original translation, is earlier than any printed edition; indeed very little over a hundred years, and very possibly less, may have elapsed between the writing of the *Regimen* and its translation into Irish." For the Latin text the editor has used two printed editions in Trinity College, Dublin: "The earlier version (J) was printed in Paris by Felix Bagault for Claude Jaumar and Thomas Julian; the editor is undated but is treated by bibliophiles as an 'incunabulum' and given the approximate date 1500." (*Regimen na Slainte*, etc., 2 vols., editor, James Carney; publishers, Irish Government Publications, 3-4, College Street, Dublin.)

# BRITISH MEDICAL JOURNAL

LONDON SATURDAY MARCH 18 1944

## HYGIENE ASPECTS OF THE EL ALAMEIN VICTORY, 1942

BY

H. S. GEAR, M.D., D.P.H.

*Lieut.-Col., South African Medical Corps; Assistant Director of Hygiene, Middle East Forces*

The hygiene story of the El Alamein victory has its logical beginning in the misfortunes experienced during the retreat of the Eighth Army from Gazala in June, 1942. Though this retreat was, in an operational sense, always under control, it created an unhappy series of circumstances for the Army hygiene authorities. First, the inevitable confusion among formations and units moving back to the El Alamein line led to decrease of supervision by hygiene officers and sections, and an understandable slackening of unit and personal standards of hygiene and sanitation. Units became dispersed; there was no time to establish control of camping sites; equipment was lost, sanitary discipline relaxed, and much ground became badly fouled. Secondly, apart from the disturbance the retreat caused in the hygiene organization, it created a new problem by sweeping back hordes of natives, Bedouins, and others, to settle in an uncontrolled mass in the rear of the El Alamein line. These natives, normally lacking any high sanitary instincts, became a serious menace to the Army, and drastic action had eventually to be taken to have them removed to harmless areas further back still. Thirdly, contributing to the problem on the eve of and during the El Alamein battle was the inclusion in the Eighth Army of formations fresh from over-seas and lacking that full respect for the question of insanitation and tropical ill-health which is gained only by experience in warm climates. These formations were also "unsalted," and hence suffered more from such complaints as "gypsy tummy" and sandfly fever than the older hoods. Fourthly, the retreat, the period of preparation, and the actual battle covered the late summer and autumn seasons, when many Egyptian health hazards are at their worst. Flies became a serious plague, necessitating special control measures. Sandflies took their toll in several base camps. The heat and dust were an added irritation, especially to new-comers.

This vast problem of hygiene was methodically tackled from the halt at El Alamein until the advance at the end of Oct., 1942. The hygiene organization was entirely reviewed and several major changes were made; the fly nuisance with its danger of spreading excremental disease was met by a special unit, the special new problems of Armoured Fighting Vehicles were gone into, and the very important problem of Army feeding was examined afresh and new ration scales and methods of cooking devised. Preparations were made for dealing with prisoners of war, who almost certainly would be lousy, and for cleaning up captured enemy areas and towns.

Once active operations had started there was little of interest concerning hygiene until the enemy broke early in November. Then the anticipated problems arose in captured territory—cleaning up fouled areas, purifying water supplies, defousing prisoners of war, and pushing forward apparatus to ensure

the cleanliness of our troops. The last-named was necessary, because typhus fever had to be borne in mind as a hazard if our troops became lousy. Hygiene officers were included in each of the new area administrations, and without delay they organized the necessary measures.

The various aspects of the work undertaken during the preliminary and operational phases of the El Alamein battle will now be discussed in detail.

### Hygiene Organization

Previous experience in the Western Desert had shown that the old hygiene organization was too rigid. Field hygiene sections were on a strict divisional and lines-of-communication basis. With the mobility of desert warfare such sections could not cope with the dispersion and changing constitution of formations, and smaller groups often had no field hygiene section assistance. Then the old defects in the method of recruiting and using unit water and sanitary duty personnel were again exposed. To overcome these defects and to meet the mobility and the kaleidoscopic conditions of desert warfare such as the Eighth Army anticipated in its projected advance, certain improvised reorganization of hygiene sections and personnel was undertaken. The principle governing this reorganization was that field hygiene sections would not rigidly adhere to their divisions, but would be held in corps and Army pools, for employment according to the needs of the situation. Its application to the Eighth Army for the battle period was made on the plan that the corps which carried out the initial assault would not follow up in the event of success but would make way for a second pursuing corps. Corps groups of three field hygiene sections each were accordingly formed. In the case of the pursuit corps, the officers commanding and detachments of the sections were allotted to brigades.

The scheme produced some excellent results; sanitary assistants were where they were required, and the workshops produced a steady flow of apparatus to supply troops moving forward into new areas. It was possible to send forward hygiene teams with stores and apparatus to captured areas, such as Mersa Matruh and Capuzzo, long before any permanent unit was available. One difficulty that arose was that the rapid changes in the composition of formations resulted in some sanitary assistants becoming completely divorced from their parent units. Unit personnel were improved by insistence on more care being given to their selection, and putting a responsibility on O.S.C. and R.M.O.s. to prevent sanitary and water-duty personnel being recruited from the useless misfits of the unit.

With the advance it was necessary to make arrangements for the sanitation of all captured areas used as lines of communication or bases. One field hygiene section carried out excellent work in depositing hygiene stores in such areas. With the establishment of sub-areas, three field hygiene sections were detailed to supervise their hygiene and sanitary restoration; two sections were allotted to Tobruk and Derna, and one field hygiene section to Benghazi.

Each new sub-area organization was provided also with a D.A.D.H., while a close liaison was built up with the Occupied Enemy Territory Administration medical organization responsible for the civilian medical services in Cyrenaica.

The bad sanitary conditions at El Alamein referred to above produced an appalling plague of flies. The emergency was quite beyond the power of the ordinary hygiene organization, so a special Fly Control Unit was created. This unit consisted of five officers and some 200 or 300 British other ranks and African pioneers, with several British N.C.O.s to act as supervisors. It was given a rapid course in fly-control methods and then sent to clean the El Alamein area of fly-breeding sources. Its work was thorough and efficacious, extending even to "no man's land," where corpses and other organic matter made one of the worst fly-breeding sources. In co-operation with field hygiene sections and unit personnel, it moved from area to area, clearing unit lines of refuse, debris, and bodies. As a measure to meet an unusual and serious emergency this temporary unit more than justified its creation.

#### Sanitation

The serious sanitary situation from July to September has been referred to above. Its particular causes lay in the general fouling of the whole El Alamein line and the areas in its rear. Vigorous action by field hygiene sections, unit personnel, and the special Fly Control Unit cleared up the region considerably, and fortunately prevented any serious outbreak of disease.

This experience demonstrated that the burial of refuse from unit lines was usually inefficiently done and contributed to the breeding of flies. Eventually incineration was accepted as the simplest and most practical method of rendering refuse innocuous. The simple oil-drum incinerator, easily improvised in the field, was most generally used. The food tin—the dominant feature of desert rations—became a menace. It was rarely emptied completely, and thus, besides increasing waste when discarded, became an annoying and difficult refuse problem. Emphatic instructions and persistent education to improve unit methods were adopted, and units gradually became more careful in clearing tins completely, burning them out, and disposing of them systematically. As will be discussed below, the return to company cooking assisted in the improvement of these conditions.

Latrines were not as troublesome a problem as might be thought. In many places the more stable camp communities were able to use deep pit latrines, though generally the rocky nature of the subsoil made deep excavations impossible. Here the petrol-tin latrine was efficacious. Daily burning reduced the dejecta to an innocuous dried mass. A simple squatting type of two-scat latrine superstructure was produced to provide the troops with at least some means of constructing field latrines. Though easily portable, being only just over 60 lb. in weight, it was a failure. With the limited transport available in the desert, units would not carry even the simplest latrine structure. Units met their latrine needs by improvisation of single seats from the ubiquitous petrol box and tin.

Waste water from field units in desert areas did not cause difficulty, partly because the water ration was so low that no large accumulations could occur, and also because the absorptive and evaporative capacity of the desert is so large.

Reference was made above to the cleaning up of captured areas. This was an immense task, as the enemy had left his fortresses, camps, and ports in an indescribably filthy condition. Previous acquaintance with enemy standards of hygiene and sanitation had shown how low they were. However, it was the advance from El Alamein which brought to light the full weakness of German and Italian hygiene organization. The enemy lines and camps at El Alamein and the bases at Matruh, Tobruk, Derna, and Benghazi were revolting in the masses of human faeces and camp debris lying everywhere. One of our hygiene officers charged with the distasteful task of supervising the clearance of the previously enemy-occupied El Alamein area reported:

"That portion of the battlefield previously occupied by the enemy is just one huge fly farm, and has to be seen to be believed. Whilst both Germans and Italians order the use of shallow trench latrines (and no oil seal), this order is scarcely ever carried out. Enemy

defensive localities are obvious from the amount of faeces lying on the surface of the ground."

The enemy paid for his contempt of hygiene, as these insanitary conditions had the inevitable result of causing a heavy incidence of excremental disease. This became such a menace to the enemy as to affect from 40 to 50% of his front-line troops, as interrogation of captured medical officers revealed. To quote one of our hygiene reports:

"It has, however, been heartening to observe the difference between the enemy sanitation and dysentery/diarrhoea rate and our own. The enemy appears to have no conception of the most elementary measures, and has a dysentery/diarrhoea rate so very much higher than ours that it is believed that the poor physical condition of his troops played a great part in the recent victory at El Alamein."

#### Rations and Feeding Problems

Previous desert operations had caused some medical anxiety over the retention of troops for long periods on a battle ration designed for one week only. This unnecessarily prolonged use of battle rations was on occasion unavoidable when troops became isolated or when lines of communication were seriously interfered with. However, it is to be regretted that in the early campaigns the danger of a low-calorie and dry ration was not always fully appreciated by some local formation supply authorities.

An attempt was made, for the El Alamein plan, to evolve a battle ration—i.e., a minimum ration of low weight and readily prepared items—which need not be limited to seven or ten days only. This ration, with 3,600 calories, adequate vitamin A, B series, and C values, composed of items available in the Middle East and not too difficult to prepare in the absence of water and cooking facilities, was rejected as being beyond the weight limits permissible by available transport. Eventually a new battle ration of approximately 3,100 calories per man per day was evolved, with the strict condition of use for not more than an absolute maximum period of ten days. It was a great advance on the old battle ration in providing variety, including such items as sausages, cheese, jam, onions, and tinned fish. Medical concern that the period of ten days should not be exceeded was fully appreciated by the "Q" authorities. The result was that throughout the October and November operations the battle ration was limited to essential occasions—in fact, only a few troops were forced to use it, and then merely for a few days at a time—a testimony to the very efficient supply arrangements of the Eighth Army.

For the rest—i.e., for most of the advance—the Eighth Army existed on the Middle East field service ration (hard) scale. This, in terms of the General Order, is the normal scale of rations, but with tinned or "hard" items substituted for fresh equivalents—e.g., tinned vegetables instead of fresh vegetables, biscuits instead of flour, etc. To prepare meals from hard-scale rations requires only the provision of boiling water. This scale was constructed under the general limiting factors operative in the Middle East—i.e., the availability of local supplies, the need to use imported and tinned items sparingly, and the limited amount of water provided for cooking in the desert. However, a satisfactory scale was produced with an average calorie value of 3,800 and the following average vitamin values: A, 2,500–3,000 i.u.; B<sub>1</sub>, 350–450 i.u.; B<sub>2</sub>, 1.3 mg.; nicotinic acid, 22–25 mg.; C, 15 mg. Yeast tablets and ascorbic acid tablets were of course available for issue on medical recommendation.

In spite of the exceedingly difficult problems of supply arising out of the rapid advance, it was not even necessary to maintain the Army on the hard scale for long periods. In a very short time after occupation, for example, field bakeries were operating in Tobruk and Benghazi and sending forward fresh bread, while consignments of frozen meat were also shipped to these ports. Fresh vegetables and oranges were supplied as opportunity allowed; but obviously, being more perishable, these could not reach as far forward as bread and meat supplies.

The construction and supply of a ration scale is only part of the procedure of feeding an army. As the Middle East campaigns have shown, however satisfactorily a well-balanced and adequate ration emerges from Details Issue Depots, much can happen to destroy its value before consumption by the troops. Apart from the time taken to train cooks in a large

ivilian army, the dispersal of units resulted in the disappearance of organized company cooking in the field. There grew up the practice of each small group, usually each vehicle crew, ending for its meals. Such vehicle or section cooking is very unsatisfactory. Well-cooked complete meals, at regular intervals, are replaced by casual feeding out of a tin. This results in waste of rations, and the debris from cooking and feeding is scattered far and wide over camping areas. A corollary to this problem arose in the case of A.F.V.s. Fighting all day, leaguered in strict black-out conditions at night too tired to look after themselves, the crews of tanks and armoured cars were too often unable to get more than an occasional bite of a biscuit. To counter these unsatisfactory methods, company cooking was reintroduced, and, except in actual highly mobile phases, most units used it during operations. For armoured units, a mobile cooking lorry was evolved by fitting a No. 2 petrol cooker and food-containers to a three-ton lorry. This simple improvised vehicle carried hot meals forward to the fighting crews and, in general, proved most valuable during the El Alamein operations.

A further special ration problem which received some attention prior to the operations was the provision of a pack ration for A.F.V.s. Tanks and armoured cars have to face occasional periods of isolation. They must be self-contained to meet such emergencies, and the provision of food, including liquids, led to the trial of the packs produced in the United Kingdom of two-men and three-men one-day rations and, on a smaller scale, of an American pack ration. In addition, most A.F.V.s were supplied with special half-gallon vacuum-flasks for hot drinks. This was a valuable measure. However, experience under desert conditions suggests that pack rations have a limited value for A.F.V.s.

Generally, the operations showed that continuous training and propaganda are necessary to ensure that all units are provided with good cooks, proper company cooking arrangements, and a fully developed sense of cookhouse hygiene and sanitation. The work being done by the Catering Advisers to the Army is going a long way to achieving the necessary improvements in the shortest possible time.

#### Water Supplies

In the initial stages of the operations the water supply was almost entirely from points on pipe-lines originating in Alexandria. This reticular system, branching out into the desert, equipped with booster pumping stations, and carrying purified water to distances of 50 miles and to within a few miles of the front line, was a triumph of the Army water engineers. It carried chlorinated water to forward units, and at least one gallon a day per man was provided in the preparatory phase during September and October.

The advance required early inspection, and usually repair and clearance, of captured water points. Hygiene personnel assisted the engineers in this duty. The majority of wells and birs had been both damaged and polluted by the enemy. The methods of pollution used were those seen in previous desert campaigns—namely, introduction of diesel oil, bone-oil, dead bodies, and filth of any kind. The destruction and pollution rarely held up our units long. Pumps were repaired or replaced and wells were vigorously pumped clear, with the addition, where necessary, of water-sterilizing powder to neutralize contamination. Hygiene personnel undertook the necessary water analysis and supervised water purification, using the standard methods of superchlorination with bleaching powder and "de-tasting" with sodium thiosulphate.

The advance carried troops considerable distances ahead of water points, and transport of water became difficult. This led to the daily ration being reduced to half a gallon for certain periods. For this purpose a variety of containers were used, the commonest being a two-gallon tin, tens of thousands of which were filled and transported by the supply organization. The most popular vessel was the captured two-gallon container—the "jerrican"—a stout metal receptacle with a good screw cap. The majority of units soon equipped themselves with these. The geology of the desert right up to Agheila, in the Gulf of Sirte, was known, so that the problems associated with saline wells were not new. Certain of these wells had to be used; in some a salinity of over 300 parts per 100,000 was

tolerated by the troops without serious results. The efficiency of the water supply was shown by the absence of any water-borne disease during the months of the attack and the advance.

#### Disease Incidence

The index of the health of the Eighth Army for the period is given by the admissions to C.C.S.s and Field Ambulances (Table I):

TABLE I.—Admissions to C.C.S.s and Field Ambulances

1942	Sick	Battle Casualties	Daily Rate of Admission per 1,000 Strength
Sept. ..	10,417	1,470	1.96
Oct. ..	11,144	7,634	1.67
Nov. ..	8,698	3,602	1.59

This table shows the excellent health of the Eighth Army in the prelude and in the actual battle. A daily admission rate below 2 per 1,000 was not only satisfactory, it was remarkable. A further feature to note is that, even in the acute battle period, admissions due to battle casualties still remained considerably less numerous than those due to disease.

The commoner causes of admissions are given in Table II:

TABLE II.—Admissions to Field Medical Units

Disease	Sept.	Oct.	Nov.
Dysentery/diarrhoea ..	1,793	1,391	1,293
Pyrexia not yet diagnosed ..	1,073	847	591
Digestive ..	933	816	517
Inflammation of areolar and skin tissue ..	927	944	622
Accidental injuries ..	858	825	736
Infective hepatitis ..	449	1,438	1,861

This table shows clearly that, in spite of modern Army hygiene progress, much preventable sickness still occurs. Dysentery/diarrhoea, inflammation of the areolar tissue, and accidental injuries, among the commonest causes of disease in the desert campaign, are still too prevalent in our armies.

Certain conditions deserve a few paragraphs of mention:

**Typhus Fever.**—Typhus does not appear in the above list of diseases; nevertheless much thought and work were given to this disease. It is endemic in many parts of the Middle East, and all the circumstances seemed set for it to become epidemic—e.g., social disorganization, spread of lousiness in civilian and, to a lesser extent, in some Army populations, etc. Adequate precautions to meet lousiness during the campaign—possible in our own troops, certain in the enemy—had therefore to be taken. Mobile disinfecting and cleansing teams were trained and pools of disinfecting apparatus and stores were created. Vaccination could not be made general owing to the then shortage of supplies.

As the Army advanced it was strongly recommended that mobile bath units and, if possible, laundries should follow. Troops were thus able to bathe occasionally, and keep their clothing clean. The organization to deal with prisoners of war had heavy work in delousing them, as infestation was high. The various measures to keep troops and prisoners of war clean and louse-free were successful, and hence typhus did not menace either our forces or our labour personnel.

**Infective Hepatitis.**—This disease still baffles investigation, and the lack of knowledge of its source and mode of spread meant that no specific preventive measures were available. Its seasonal incidence (late autumn) affected the Eighth Army during the battle phase, large numbers of cases being admitted in October and November. It was most prevalent first in a New Zealand division, but subsequently caused as many cases in Australian and U.K. divisions. From Table II it is apparent how serious a cause of disability it was in the later stages of the battle. This disease is an annoying element in wartime, not because of its seriousness to the individual, but because it immobilizes large numbers in hospital for not inconsiderable periods of treatment. Every effort, both clinically and epidemiologically, was made to determine its cause and mode of spread, unfortunately without success.

**Desert Sores.**—This condition, or group of conditions, was troublesome. Its incidence, too, was highest in the desert in

autumn. The aetiology and epidemiology, as with infective hepatitis, are not definitely known. Controversy thus had free scope, and included the argument that a vitamin deficiency, especially of vitamin C, is the cause. There seems to be no justification for this extreme view, which unfortunately received much publicity. This did a certain amount of harm in producing an unjustified distrust, and even an anxiety, about the adequacy of the various Army ration scales. These scales, as discussed above, were prepared with full appreciation of the vitamin needs of the soldier. The generally accepted Middle East opinion of this condition may be stated as follows:

(a) It is a vague condition covering a whole variety of ulcerative skin lesions. (b) A minor injury is an antecedent in the majority of cases. Scratches, bruises, insect bites, etc., are the commonest injuries, and their location on exposed parts, such as forearms, hands, and knees, is thus directly parallel with the commonest sites of desert sores. (c) On occasion troops on full fresh rations have shown a high incidence, while, conversely, troops on the so-called "hard" scale have frequently been free of the affliction. There has not been any correlation, therefore, between adequacy of rations and incidence of the disease. Further, in cases of desert sore no true evidence of avitaminosis (scurvy, etc.) has been reported.

Accepting the correlation of sun, dust, dirt, flies, and minor injuries with the incidence and site distribution of so-called desert sores, protective action on general lines was planned. An attempt was made to get all troops into slacks and long-sleeved upper garments to cover the most susceptible exposed areas. Every effort was made, too, towards improving the washing facilities by pushing forward bath and laundry units, by making available simple showers, and by supplying sea-soap. Warnings and instructions to personnel and to regimental officers of the necessity for early treatment of minor cuts, bites, and bruises were issued, and the necessity for seeking medical treatment of sores was emphasized. An experiment in the use of an emollient cream on exposed parts to reduce injuries and to soften and protect the skin could not be completed owing to the operations. All in all, desert sores seemed to be relatively less in incidence, and were certainly less severe, in 1942 than in 1941.

**Dysentery/Diarrhoea.**—During the early preparatory stage, and even right into the start of the battle, these diseases caused much anxiety. As indicated above, it was a combination of seasonal changes as well as control measures which reduced the fly population, and hence the incidence of dysentery and diarrhoea. To repeat, these diseases were the result of the insanitary conditions arising out of the general fouling of the battle area of El Alamein due to the retreat and the bad disposal of waste, especially food. Though to us the excremental diseases were a bad enough problem, they became a crippling menace to the Germans and Italians owing to the absence of any hygiene control by them. Our troops, too, had the benefit of the efficient protection afforded by our T.A.B. vaccine.

**Heat and Sun Effects.**—The desert on the whole has not been intolerable on account of heat and glare. Wherever possible, troops from temperate zones have served a preliminary period of 3 to 6 weeks in relative quietness in the Canal Zone before proceeding to the Western Desert. This has proved an important process of acclimatization not only against heat and sun, but also against many of the dietetic and other irritations of an Oriental location. Unfortunately, certain reinforcements for the Eighth Army at the critical stage at El Alamein had to be pushed forward sooner than usual, and these at first felt the desert conditions to a certain extent. No cases of heat- or sun-stroke, or other effects due directly to exposure to heat or sun, have been reported. In fact, accepting modern views of the mode of action of temperature, light, and humidity on the human organism, it was decided that the bulkiness, fragility, short life, and distaste by the troops of the huge sun topee did not justify its retention for Middle East troops. Its abandonment has had no evil results. Even in tanks and armoured cars the desert heat led to no disastrous incapacitation. The high evaporative power of the desert air saved the heat-regulating mechanism of the body from any undue strain, so that as long as the tank engine, and hence the engine-ventilating system, was pumping air through the vehicles conditions were not dangerous. In the desert, therefore, there was no call for special air-conditioning devices for A.F.V.s. The

indirect effects of sun, dust, and irritation on the skin have been referred to in the discussion on desert sores.

Glare requires a short comment. The new-comer to the Middle East, alarmed by tales of the dangers of the desert sun, is usually conspicuous by the blackish sun-glasses he affects, but the older "hand" generally discards them. This indicates the Middle East policy on sun-glasses, which is that for the vast majority of individuals they are quite unnecessary under all normal conditions. In fact, such devices, by reducing the tolerance of the eye to light and by not affording it opportunities for adaptation—which quality it possesses in high degree—may actually be harmful. A wearer of dark or tinted glasses in the relatively non-glaring atmosphere of, say, Cairo, if suddenly transported to the white-sand areas of the Western Desert, will suffer intensely and be crippled in vision because his eyes have never been exercised in toleration to light. Sun-glasses have accordingly, in spite of certain demands, not been made a general issue in the Middle East, though in conditions in which glasses are both protective against dust and glare special issues have been made to limited groups of drivers, A.A. gunners, etc. No untoward damage has been reported by ophthalmologists as a result of this policy.

**Accidental Injuries.**—Accidents are as alarming a feature of modern society at war as they are during peace. This largely unnecessary drain of man-power and strain on medical facilities has occupied the attention of several branches of Army administration in the Middle East. Analysis of motor accidents, exhortations for care in handling petrol, instructions in precautions in handling explosives and mines, seem to have had only a gradual influence on the frequency and degree of accidents. Burns were the form of accident which came into prominence during the El Alamein phase. It was noteworthy that over the whole period accidental burns usually outnumbered those due to enemy action—e.g., setting tanks, etc., on fire. Petrol, of course, was the origin of most of the accidental burns seen in the Eighth Army. It is surprising how long it takes the average soldier to gain that essential healthy respect necessary in handling that extremely volatile and inflammable fluid. Lacking fuel in the form of coal or wood, fire in the desert was made with petrol for all purposes—cooking, boiling water, sterilizing apparatus, etc. There was evolved the so-called "desert stove"—a petrol tin, suitably vented, containing a small quantity of sand on which petrol was poured. Too often the inexperienced replenished this type of fire by flinging quantities of petrol on to the hot sand, with the inevitable explosion and burns. Many serious burns followed the use of petrol as an insecticide in dug-outs and other ill-ventilated premises. The lighting of a cigarette in such a heavily charged atmosphere, too, produced unfortunate results. A useful and simple safeguard against serious burns came to light in the investigation by No. 1 Medical Research Section of burns in A.F.V.s during the retreat from Gazala—viz., the great protection given by ordinary clothing. Consequently, instructions were issued that tank crews were to wear slacks to cover the knees, and sleeves down to cover the arms. Ordinary accidents should receive more and more attention from military hygiene, as they are a most serious cause of army inefficiency. It is a difficult subject, as their variety and causation are so complex, especially in a hastily trained army handling so many powerful mechanical forces and agents—explosives, volatile fluids, gases, armoured fighting vehicles, and ordinary transport.

### Summary and Conclusion

The retreat by the Eighth Army from Gazala in June, the defensive phase on the El Alamein line from July to October, and the eventual attack and victory in October and November, 1942, created the conditions and setting of serious and complex preventive medical and hygiene problems.

Questions of sanitation and the spread of excremental disease, of the prevention of typhus, desert sores, and other diseases, of the provision of adequate properly balanced rations and a pure water supply; and of dealing with the dangers of captured fouled areas—all were studied and, on the whole, successfully solved. In the opposite camp of the enemy, as captured ground and documents showed, hygiene was not energetically studied, and to-day the Italians and the Germans must regretfully realize that their neglect contributed seriously to their inability to resist our attack. A front-line force with 40 to 50% of its strength affected by dysentery and

diarrhoea can scarcely be called a vigorous army, and this was the incidence in Italian and German units.

In contrast, the Eighth Army in October and November was probably as fit mentally and physically as any army has ever been. The contribution of preventive medicine to this standard can be measured from the degree of success achieved in protecting our troops from infectious disease, in maintaining a high level of physical fitness, in ensuring adequate rations and water supply, and in adapting so far as possible the Army's clothes, fighting, and other equipment and camping conditions to accepted physiological standards. The hygiene officers and other ranks of the Eighth Army, by their enthusiastic application of modern public health principles to a heterogeneous force in a difficult environment, did good work. They—hygiene men recruited from the United Kingdom, New Zealand, South Africa, Australia, and India—may not have the glamour, glory, and excitement of their brothers in the clinical units, the field ambulances, and casualty clearing stations, of the medical services, but they have the satisfaction of knowing that the health of the Eighth Army, and hence in large measure its physical and mental capacity for forceful action, shown at El Alamein, owed much to them.

I have to thank the Director of Medical Services for permission to publish this paper. I am also very much indebted to Col. A. E. Richmond, Deputy Director of Hygiene, for his general guidance and advice in its preparation, and to Brig. J. Walker, Deputy Director of Medical Services, and Lieut.-Col. R. R. Leaning, Assistant Director of Hygiene, Eighth Army, for certain of the material included.

## A STUDY OF A SELECTED GROUP OF WOMEN EMPLOYED ON EXTREMELY FINE WORK

BY

IDA MANN, D.Sc., F.R.C.S.

AND

DOROTHY ARCHIBALD

(Oxford)

The ability to perform fine work for long periods without ocular fatigue or symptoms of any kind depends on a variety of factors at present incompletely known and of the relative importance of which we have only an imperfect idea. The obvious factors to be taken into account are the individual's refraction, visual acuity, muscle balance, accommodative power, and psychological adjustment to the work. The present study was undertaken with a view to establishing what degrees of these make for success in close work, and to assess their relative importance. Most previous analyses of the condition of healthy eyes have been made on large groups of hospital or private patients, and are therefore probably not entirely representative, since the patient had himself come for examination and thus could not be regarded as entirely symptom-free. An attempt to correlate the findings in one field (convergence deficiency) between a group of private patients (unselected) and a group of R.A.F. recruits, without symptoms, has already been made,<sup>1,2</sup> with the result that the difficulties of the subject have become more apparent. The outstanding feature which emerged was the high percentage of convergence deficiency, and indeed of all phorias, in the group of 7,019 recruits who made no complaint of symptoms. In the group of 6,400 private patients with which they were compared the number complaining of symptoms associated with convergence deficiency was much higher, though the incidence of such deficiency in the whole group was actually lower (2 to 3%) than in the symptom-free recruits. It therefore seemed to us that the answer might partly lie in the kind of work done by the two groups. In the group of private patients the number who were engaged in close work was much higher than that in the recruits, and it thus appeared likely to be profitable to study the characteristics of a group doing extremely close work for long hours without symptoms. In this way one might find certain characteristics in which such a group differed from the two previously selected groups. The following study was undertaken with this end in view and, although the number examined is extremely small, the results are uniform enough to be significant.

The work was made possible by the courtesy of a leading firm of electrical engineers actively engaged in the manufacture of electric lamps. Our sincere thanks are due to them for their co-operation and assistance. The group investigated consisted of 28 women and girls between the ages of 15 and 40,

employed on what is known as "spiral inspection." This job is a suitable one for our purpose, since it demands an extremely high degree of visual concentration at an average distance of 250 mm., thus requiring accommodative effort and convergence to a greater amount than ordinary clerical work, as well as a high degree of visual acuity. The group comes into being by a process of natural selection, a number of girls being tried out on it and only those who can do it accurately without fatigue being retained. In this way the group should indicate the characteristics of persons suited to continued close work.

The work consists in sorting (by direct inspection on an illuminated green glass plate) the spiral filaments for electric-light bulbs according to their perfection, all flawed filaments being rejected. The smallest spiral dealt with has 1,400 turns to the inch. The diameter of the wire is 0.00057 in. and the separation is 0.00059 in. The girls look for two turns of the spiral in contact, for gaps, or for unevenness of pitch and of total length of the filament. This length is 60 or 100 mm., and must be accurate to 0.25 mm. A good worker will sort 10,000 filaments a day, and is actually at work 40 hours of a week of 47 hours. The average number sorted is 6,000 a day. The work begins at 7.30 a.m. At 9.30 a.m. there is a ten-minute break, at 12 noon an hour's break, and at 3 p.m. a ten-minute break. Work ends at 5 p.m. The girls do not wear any special optical appliance. They are provided with loupes magnifying about 8 diameters or less, but they use these only occasionally, when in doubt.

The degree of visual acuity involved is interesting. Using Gullstrand's constants, and calculating the size of the retinal image of the separating gap between the smallest coils (0.00014 in.) at a working distance of 250 mm., we find:

$$\text{Size of image} = \frac{1.4}{39.37} \times \frac{17.05}{250} = 0.0025 \text{ mm.}$$

Since the diameter of a foveal cone is approximately 0.002 mm. and the angle  $\theta$  usually given as  $24.14''$  it is obvious that we are working very near the limit of resolvability for the human eye. The 28 girls interrogated had been employed for periods varying between 6 months and 13 years and made no complaints of eye strain, though six said the job was rather dull and uninteresting.

The girls were tested for visual acuity on the Snellen and Jaeger types, for muscle balance (Maddox wing, Maddox rod and cover test), for stereoscopic vision, for convergence, and for voluntary convergence. They were also interrogated about their general health and their hobbies to see whether after working-hours they chose occupations involving further close work. Since we have always strongly suspected that there is a large psychological element in the production of asthenopic symptoms, one of us (D.A.) performed a group Rorschach test, using the Harrower-Erickson<sup>3</sup> multiple choice technique, with a view to estimating the psychological adjustment of these 28 workers. The Rorschach method<sup>4</sup> of personality evaluation has been in use for 20 years and has been validated by a great deal of research, carried out on normal persons, psychotics, and patients with organic nervous disease. It is in use in the Armies of most of the nations engaged in the present war. It consists in showing the subjects a set of standardized ink-blot, and recording what they see in the blots, and what features they use in them to construct the images. Until recently it remained an individual test, but a modification for rapid screening-out of maladjusted subjects has been devised in America to meet the wartime need for dealing with very large groups of individuals. The ink-blot are projected on to a screen and the subjects are presented with a series of responses and asked to mark those which best describe what they see in the blots. The responses have been chosen from the most usual ones found in the records of a thousand subjects whose psychological adjustment is known. This modification does not make detailed individual analysis of personality possible, but provides a method of rapid assortment into groups. It is undoubtedly susceptible of improvement, but it already seems to be the best test available for forming a general estimate of the emotional adjustment of groups of unknown subjects.

The Rorschach test is based on the principle that the meaning with which an individual invests a stimulus that is in itself meaningless reveals the inner organization of that indi-

vidual. If one subject sees an aeroplane, another a radiograph, a third a bear, and a fourth a man in the same ink-blot, then it is certain that something different goes on in these four individuals between the moment when the same physical stimulus reaches their retinae and the moment when they communicate their reactions. The assumption made is that these differences are meaningful and can be interpreted on Rorschach's principles.

It is claimed that the test makes it possible to estimate the "variety of an individual's psychic reactivity, the degree of his social or affective adjustment, the extent to which his inner life is integrated and constructive or disorganized by more primitive drives or undue anxiety."<sup>5</sup>

Our findings can be arranged under the following headings: age and time on present job; refraction and visual acuity; spectacles worn or not; master eye and hand; muscle balance, distance and near; presence or absence of headaches; recreations and attitude towards work; results of psychological test.

#### Age and Time on Present Job

The ages varied between 15 and 40, the average being 24 years. The shortest time on the job was six months and the longest 13½ years. The average was four years, but seven girls had been at the work for more than five years. If the girl is unsuited to the work this is discovered almost at once. Breakdowns, once the job has been mastered, do not seem to occur.

#### Refraction, Visual Acuity, and Spectacles

The refraction in each case was done without a mydriatic. The accompanying Graph shows the distribution of errors in

percentages. The high peak represents the present group; the three almost coincident lower curves are percentages taken from Wibant, Scheerer, and Brown, quoted by Dunstan.<sup>6</sup> The grades are taken at intervals of a dioptre, the refraction being reckoned as the average between the two meridians (as advocated by Edward Jackson). It will be seen at once that the group contains roughly twice as many individuals with a refraction between +1 and -1 as do the groups of other observers. A refraction approximating to emmetropia would therefore seem to be one of the factors influenced by the selection. It is not, however, the only factor. The two highest errors found were +4.5/-0.5 and -2.75/-0.75, both in girls entirely free from headaches or eye strain, but wearing their correction. The hypermetrope had a convergent strabismus in addition. In 22 of the 56 eyes refracted the error was very slightly minus, which is rather more than would be expected in the general population, though in standard figures, such as Hertel's<sup>7</sup>—who in 12331 eyes found 10 to 15% myopic, 30% emmetropic, and 50 to 55% hypermetropic—it is never clear whether myopia of less than one dioptre is counted as emmetropia or not.

Eleven of the 28 girls wore their correction at work; seven more had bought glasses from sight-testing opticians, but never wore them. Five of the 56 eyes were absolutely emmetropic so far as could be made out without a mydriatic—a high proportion compared with the generally accepted figure of 1 to 2% for the general population. All the eyes except two (the partially amblyopic eye of the squinter mentioned above and the left eye of an almost emmetropic girl with a small corneal scar) had full visual acuity, varying from 6/6 to 6/4. It would appear that a low error of refraction is an advantage, but that a moderately high error, if corrected, is no bar. The correction of the low errors does not seem to be necessary.

#### Master Eye and Hand

Three of the girls showed a left master eye; one of these was left-handed, one ambidextrous, and one right-handed. The rest were right-eyed and right-handed.

#### Muscle Balance

The results in this group of tests are very interesting, as they show a much higher degree of binocular vision than was found in the analysis of the symptom-free R.A.F. recruits. Considering distance tests with the Maddox rod first, we found in 15 girls no imbalance, in four a slight exophoria of less than 1Δ, and in nine an equally slight esophoria. In none was there any vertical imbalance. (Grieve and Archibald found 5.3% with deviations of more than 4Δ horizontal or 1.5Δ vertical in their R.A.F. group.)

The results on the wing test were equally good. Twenty-two of the 28 showed a lateral deviation of 2Δ or less, and all of these saw the arrow quite steady (11 saw it dead on 01 all the time) and with no tendency to slip on the scale. Of the remaining six, two saw the arrow slip out to 4Δ, one to 6Δ, and one to 3Δ (esophoric), and so would have been counted normal by the usual standards, leaving two only really abnormal. One of these—the squinter, with high hypermetropia—saw the arrow at 11Δ (esophoric), but usually suppressed her left eye; the other, a left-handed girl with doubtful binocular vision for near objects, also saw it at 11Δ (esophoric). This is very different from the findings of Grieve and Archibald, who stated that 23.6% showed lateral deviations of 4Δ or more and vertical of 1Δ or more. It would appear, therefore, that orthophoria for near vision is more definitely selected than is approximate emmetropia.

Further investigations into the binocular condition at the near point were done, using a stereoscope, and testing also convergence, voluntary convergence, and the results of the cover test.

#### Stereoscopic Vision

A simple stereoscopic card (the two arrows) was first shown. The girl with the accommodative squint had doubtful appreciation of depth, but all the others except one (also doubtful, but apparently otherwise binocular) saw the perspective correctly at once. They were then shown a very difficult stereoscopic test which has so far not been extensively used. It is one of the set of rotating stereograms (Livingston) used in the R.A.F., and represents a variety of small objects (camels, palm trees, and pyramids) which should appear at varying depths that are stereoscopically unconnected with and often at variance with the relative size of the objects. Thus, for example, the largest camel is not the nearest, so that judgments based on size and probability are ruled out. If all the objects are seen in their right relationship the person has better than normal stereoscopic vision. Of these 28 girls, six saw all the objects correctly. In a control group of 30 nurses and medical students of the same ages picked at random, only two could perform this test correctly. Of the remaining 22 girls, six got some of the objects correctly placed and 16 could not do the test. This is a performance much better than the average as at present known for this test.

#### Convergence, Voluntary Convergence, and Cover Test

Convergence on an object held up to four inches from the eyes was present in all. In one it was poorly maintained, this girl being the non-squinter with doubtful stereopsis mentioned above. Voluntary convergence was present in 23 of the 28, though it was fair in three and poor in four of them. In the five in whom it was not present the cover test showed convergence in one and divergence in five. In the 22 of the 23 with voluntary convergence the cover test showed nothing and the remaining one a slight left exophoria. This girl had a myopic astigmatism, but worked without glasses and stated that her eyes were sometimes tired. She had been on the job for four years, and liked it and did not want to give it up. She spent a lot of her spare time reading. The five without voluntary convergence are interesting. One was the squinter, who of course used only one eye for the work. One was emmetropic and worked without difficulty. She stated that she thought she had lost the power of voluntary convergence after diphtheria, which had involved her eyes. Another

emmetrope complained of tired eyes and occasional headaches after six months on the job. The fourth complained of sudden pains in her eyes and "blackness" suggestive of migraine. The fifth was myopic and tended to read monocularly. She had occasional migraine. She had done the job for seven years, but did not like it much.

### Headaches

Eleven girls said they never had headaches, five said they had a headache at their period, and three had a history suggestive of migraine. Of the eleven without headache all had voluntary convergence, or were monocular for near work. One stated that she had headaches at the cinema but not at work; another said that being indoors too much gave her an occasional headache. There was no serious complaint of either headache or eye strain. Six who did not like the job complained vaguely of tired eyes. One was aged 40, and showed an exophoria of 6Δ on the wing test and poor voluntary convergence; three had no voluntary convergence (described above).

### Recreations

An attempt was made, by asking whether the recreation of choice was one involving close work, to ascertain whether there was any sense of ocular discomfort after work. The recreations mentioned in order of popularity were reading (13 times), sewing, knitting, and cinemas (7 times each), dancing (5 times), cycling (4 times), swimming, walking, and other outdoor things (3 times each), housework and gardening (once each). Most of them mentioned more than one hobby. It would appear, from the large number who put reading and close work first, that it was unlikely that there was any case of true eye strain in the group. None of the girls considered that the work had hurt their eyes in any way.

### Psychological Test

The result of this test shows that, out of the total of 28 workers ranging in age from 15 to 40, 21 must be considered normal and well adjusted. Of the remaining 7, 4 may be borderline cases who, if subjected to severe strain, might well break down and develop psychological difficulties, and 3 show definite signs of disturbance. The accompanying tables show

TABLE I.—Percentage in All Groups Above and Below the Danger Line

Groups	No.	Stable Subjects %	Unstable Subjects %

Mental patients (U.S.A.) .. .. .	143	13	10	14	62
Total tested .. .. .	779				

Comparison of the results of this test on these workers with the results on the other known groups shows that the factory workers come out where they might be expected to be found: they are below the superior adults, the unselected adults, the student nurses, and the women in the Services. In the highest group they have a smaller percentage than the prisoners or the students who are in the hands of a psychiatrist, but they have a much higher percentage of "good average." Their percentage of "seriously disturbed" individuals (11%) is lower than that of the prisoners (15%) or of the students (30%), but markedly higher than that of the superior adults, both English and American. It is also higher than among the student nurses and women in the Services, who will, of course, have been carefully selected on the basis of screening tests. The workers appear to compare badly with the American group of "unselected adults." Unfortunately Harrower-Erickson gives no information on the make-up of this "unselected" group, but if it was a true random sample of the adult population we must assume that these workers include some neurotics who make satisfactory adjustments at this particular job. This may well be true, and, if it is, it would indicate that this type of work suits some types of neurotics. Obsessionals—for example, compulsion neurotics—and some anxiety cases might find a haven in this work, since it makes little or no demand on intelligence or responsibility and reassures them by its monotony.

It should be stated that most of the disturbing signs shown by these workers are signs of general or focal anxiety, and it may be that some of this can be accounted for by the fact that they are living through a period which for many of them must involve acute emotional strain. Those with the least psychological resistance are likely to show more signs of disturbance than they would in time of peace.

Study of individual records shows some interesting correspondences with the information gathered from the girls when their eyes were examined. Of the six who said that they did not like the job two show signs of considerable disturbance; both give very meagre and attenuated records. One of these—the only one who tried to avoid doing the psychological test—revealed in her interview that she had had a nervous breakdown and still suffers from night terrors. The other complains of headaches at the back of her head, which she says she has always had; and she states that her mother has them too. Neither of these girls has full voluntary convergence. Of the remaining four, two were previously cooks and much preferred that work to their present job, which they said they would leave directly the war ended. Their responses also revealed instability. Of the remaining two, one had a history suggestive of migraine, but her Rorschach reaction was normal; the other gave a very excellent Rorschach result, which shows that the job is not using her full ability.

Of those showing the highest scores (best adjustment) one was the charge hand who had been on the job 13 years, four were perfectly content in the job, and two were superior girls who thought the job monotonous and were obviously capable of taking more responsibility than they were given. It is of interest that the only girl whom the management considers unsatisfactory is the one who gives the best Rorschach record of the whole group. She has a very rich full set of responses with no single weak sign. It may well be that she is too good for this job and is wasting a large part of her ability.

### Conclusions

In studying this group of people selected by trial and error and found empirically to be able to do excessively close work without fatigue, certain characteristics stand out—namely, their extremely highly developed stereoscopic sense and muscle balance at the near point. This would appear to be more characteristic and more important than their refraction, though selection has worked to improve the average of this as well. The few complaints of dislike of the job came from persons with phorias rather than with high refractive errors. This is encouraging, since it should mean that by treating phorias more people could be fitted for close work.

From this it follows that if one wishes to predict whether any given person will be suitable for continued close work, certain criteria can be suggested. The person should be

orthophoric on the wing test, should have no hyperphoria, and should have well-developed stereopsis and a corrected visual acuity of 6/6. Failing this, the subject should be monocular for near vision.

On the psychological side it cannot be claimed that testing is necessary for the selection of workers for this particular department, since the management, from long experience, only tries girls whom it has good reason to think will prove suitable. Those who show fatigue during the training period are not retained. We are not in a position to generalize as to what type of human being is best suited for this work, but, on the evidence of this one test, we might say that, although a few neurotics may be able to do it, the safest group are the good average people who are not unduly blessed with imagination nor are highly intelligent—a statement which probably holds true for any repetitive factory process. If, therefore, selection tests in industry were contemplated, the factors on which judgment of fitness for close work should be based would appear to be, in order of importance: (1) binocular balance: (2) refraction; (3) psychological stability.

It would seem likely to be of advantage, in industrial and other processes such as that described, to test the candidate with these points in mind before starting training, which otherwise may only prove to be a waste of time.

## THE ACTION OF ELECTRIC BLANKETS

BY

G. MALCOLM BROWN, D.Phil.Oxon, M.R.C.P.

AND

K. MENDELSSOHN,\* Ph.D.Berlin

(From the Nuffield Department of Clinical Medicine, Oxford)

In a previous communication (Brown, Evans, and Mendelsohn, 1943) the action of radiant-heat cradles was recorded. Continuing this work on heating apparatus in clinical use, we have carried out an investigation on the action of electric blankets. These two methods of supplying heat to the body differ very much in their physical aspects, for the cradle acts mainly by heat radiation,\* whereas heat from the electric blanket is conveyed to the patient almost exclusively by conduction. It seemed of interest, therefore, not only to observe the action of the electric blanket in clinical use, but also to compare the effects of both methods on the same patients under similar conditions. The difference in physical action between the two methods naturally entails certain differences in efficiency, applicability, and supervision, and one of the objects of this investigation was to decide which method could be used most advantageously for different purposes.

The electric blanket which we used had been supplied by Thermega, Ltd. It is a large heating pad of the ordinary type, measuring 33 by 46 in. Heat is generated by a current (mains supply) passing through a resistance element. The maximum temperature of the electric system is limited by thermostatic control of the current supply. The average consumption was found to be about 120 watts, and varied but little with the temperature of the heating element. The current passing through the blanket was 0.511 amp. at the outset, 0.512 amp. after 1 hour, and 0.517 amp. after 4 hours. The total amount of heat produced by the blanket is therefore about 100 kilocalories per hour.

The temperature of the heating element proper must be kept low for reasons of safety. Since the material between the actual heating wire and the skin of the patient is probably opaque for far infra-red radiation—the only radiation which the heater emits—it appears reasonable to assume that practically all the heat taken up by the patient is by conduction.

## Physiological Action

The method of clinical use of the electric blanket consists in putting the blanket on the bed, covering it with an ordinary woollen blanket, and placing the patient on top of this. For reasons which we shall discuss later, the method of covering the patient has a very considerable influence on the rise in body temperature. In our case one woollen blanket was used and the patients were allowed to put their arms on top of the cover. By placing a thermometer on the bed in the position to be occupied by the patient it had been found that temperature equilibrium was attained only after about two hours (Fig. 1). We therefore heated the blanket for at least two hours before the patient was placed on it.

FIG. 1.—Curve showing the temperatures recorded by a thermometer placed in the position of the patient above the electric blanket.

The tests were carried out on volunteers, who were submitted to heat treatment with the blanket for periods ranging from 1½ to 2 hours. The body temperature was determined in some cases orally, using an ordinary clinical thermometer, and in others with an electric recording rectal thermometer. One characteristic temperature/time curve showing the results with the electric blanket and the radiant-heat cradle is reproduced in Fig. 2. Both these curves show that the first reaction to

FIG. 2.—The body temperature of a subject heated first with the electric blanket and later with the radiant-heat cradle.

the application of heat is a decrease in body temperature. This peculiar phenomenon had already been observed in 9 out of 12 experiments with the radiant-heat cradle. Of the 7 cases

\* In receipt of a personal grant from the Medical Research Council.

† As has been emphasized before (Brown, Evans, and Mendelsohn, 1943), heat conduction and convection through the air inside a cradle also play an important part in conveying heat to the patient, but it is not known how large this part actually is.

investigated with the blanket, 5 showed this initial temperature decrease. It therefore appears that the phenomenon is quite generally a result of heat application and is not confined to heating by radiation. It was noted, however, that, whereas the temperature drop in the cradles occurred at 5 to 20 minutes after the beginning of treatment, it occurred with the blanket only at 30 to 90 minutes after heat was first applied.

The average rise in body temperature which we observed when using the blanket was about  $0.45^{\circ}\text{F.}$  per hour (see accompanying Table). This is much less than has been reported

Table showing the Rise in Body Temperatures, the Heat apparently taken up by the Subject, and the Heat generated by the Apparatus in 14 Experiments

Case No., Sex:	1 M	2 M	3 F	4 M	5 M	6 F	7 F
Time (min.)	120	120	120	90	90	105	90
$\Delta T^{\circ} (\text{F.})$	1.7	0.5	1.1	0.4	0.6	0.6	0.7
$Q^{\circ} (\text{cal.})$	63	20	35	15	23	17	18
$P^{\circ} (\text{cal.})$	200	200	200	150	150	175	150
$\Delta T^{\circ} (\text{F.})$	2.1	1.0	1.6	2.5	0.8	0.8	0.5
$Q^{\circ} (\text{cal.})$	78	40	51	93	31	22	21
$P^{\circ} (\text{cal.})$	970	1,200	970	780	780	875	750

$\Delta T^{\circ}$ : Rise in body temperature.  $Q^{\circ}$ : Heat apparently taken up.  $P^{\circ}$ : Heat generated by the apparatus when the subject was treated with the electric blanket.  $\Delta T^{\circ}$ ,  $Q^{\circ}$ ,  $P^{\circ}$ : The corresponding figures when the subject was treated with the radiant-heat cradle.

by others. Neymann and Osborne (1934), for instance, find an hourly rate of rise of  $1.1^{\circ}\text{F.}$  in rectal and  $1.8^{\circ}\text{F.}$  in axillary temperature for the first two hours of application. This discrepancy can probably be explained by the method of covering the patient. If the electric blanket is wrapped around the body and the arms are kept in, the rate of temperature rise is bound to be greater. In fact, as Epstein and Cohen (1935) have reported, a rise in body temperature of  $1.6^{\circ}\text{F.}$  to  $1.8^{\circ}\text{F.}$  per hour can be produced without the use of any heating equipment simply by wrapping the patient tightly in a number of blankets and a rubber and a canvas sheet.

At first sight it seems astonishing that, merely by preventing the loss of metabolic heat, increases in body temperature occur which are about as high as those obtained with quite powerful external heating methods. An explanation for this can be found by comparing the amount of heat actually taken up by the patient from the external heat source with his own metabolic heat production. In the Table the total heat ( $P^{\circ}$ ) supplied in our tests by the blanket, and the heat ( $Q^{\circ}$ ) apparently taken up by the patient, are given. This amount of heat "apparently taken up" represents, however, not necessarily the real amount of heat received by the patient, since the calculation does not take account of any change in the rate of loss of heat by the patient through physiological processes. The total heat generated by the blanket (100 cal./hour) is of the same order as the metabolic heat itself. Only 15% ( $\frac{Q^{\circ}}{P^{\circ}}$ ) of this heat supply, however, is apparently taken up by the patient. It is therefore not very surprising that an arrangement which prevents the loss of part of the metabolic heat will heat the patient as quickly as an electric blanket, which, after all, delivers to the patient approximately only the heat which he normally generates himself.

#### Comparison of the Electric Blanket with the Radiant-heat Cradle

The same 7 volunteers were subjected to heat treatment of equal length with the shielded cradle described by us in our earlier paper. The results are given in the Table. As can be seen in Fig. 3, the cradle heats about twice as much as the blanket. The method of treatment with the cradle was that previously recommended by us. Twelve bulbs were used at first, and the number was reduced to 8 bulbs after 20 to 30 minutes. The average rate of temperature rise observed in the present research was  $0.8^{\circ}\text{F.}$  per hour. Considering the scatter, this result is in remarkable agreement with our previous work, when we found the rise to be  $1^{\circ}\text{F.}$  per hour. A slightly lower value was to be expected in the present tests, since in the first investigation 12 bulbs had been used throughout. The temperature rise produced with the blanket was about the same as that observed with the unshielded cradle used in the orthodox way.

FIG. 3.—The rises in body temperature observed in 7 subjects treated with the electric blanket and the radiant-heat cradle.

While it is true that the shielded cradle supplied nearly twice as much heat to the patient as the blanket, it is less economical, because it produces five times as much heat at the source ( $\frac{P^{\circ}}{Q^{\circ}}$ ). The heat taken up by the patient is only about 5% of the total heat generated ( $\frac{Q^{\circ}}{P^{\circ}}$ ). As the difference in the cost of electricity can in most cases be neglected, the cradle's lack in economy is not very serious.

Thinking, however, in terms of absolute quantities of heat taken up by the patient, the low efficiency of the cradle compared with the blanket requires some explanation, since the total amount of heat generated by the former is about five times the metabolic heat. It appears to us that the two main factors which lower the efficiency of the cradle are heat loss to the outside and heat loss from the patient by perspiration. With the blanket, on the other hand, both these factors are reduced to a minimum, since there is less heat loss from the heating element, which is placed between the bed and the patient, and since the covering blanket contains practically no space for the evaporation of sweat. Experiments to improve still further the efficiency of the cradle are in progress.

#### Discussion

The electric blanket has advantages which recommend it for certain clinical uses. It is safe and causes no discomfort at ordinary heating rates. When used to produce artificial hyperpyrexia there have been cases of fire due to a fault in the heating element, but we know of nothing similar occurring in ordinary use. It requires little supervision. None of our volunteers complained of any skin discomfort, and the risk of burns is less than with an unshielded cradle. The shape and the position in the bed are but a small inconvenience to the nursing staff. A most important disadvantage, however, is the long period taken to reach the maximum temperature and the lack of variability of control. With the cradle it is possible to raise the temperature of the air around the patient's body very quickly to a given degree and to maintain it at that level for an indefinite time. Even at its maximum temperature the electric

blanket raises the body temperature only half as quickly as the cradle. The cradle is the better instrument when heat is required quickly and in large quantities. When forethought is possible and less heat is required the blanket is to be preferred. To warm the waiting bed for the patient or to keep him warm out of doors in cold weather the blanket should be used, but when heat is prescribed for the victim of an accident the heat cradle is indicated.

The administration of heat presents several problems, aside altogether from the question of its therapeutic value, which we do not wish to discuss. For instance, we are at a loss to explain the decrease in body temperature which occurred in the first period of treatment in a great majority of our cases. At the same time the skin temperature was rising rapidly to its final value. This effect of an artificially increased skin temperature on the body temperature needs more investigation. We must also keep in mind that the physiological reaction in local application is probably quite different from that in general application of heat. The same dose of radiated or conducted heat may result in a very different response, depending upon its localization. It should be clear what is needed when heat is prescribed—an increase in body temperature or merely the application of warmth to the skin. Each requires its own mode of application. A hot-water bottle is an easy way to warm the skin, and in many cases that is all that is indicated. However, 500 c.cm. of water cooling through 50° C. does not make an important contribution to body heat, and where this must be increased the shielded cradle is the instrument of choice. It is clear from our observations that in the healthy volunteer under treatment the rate of heat loss is greatly increased. His skin is flushed and soon covered with perspiration. The effects on the temperature-control mechanism in the cold shocked patient may not be the same. A completely rational therapy will have to wait on a further knowledge of the relation of all these factors.

#### Summary

The electric blanket acts by conduction of heat to the patient. Even when the bed is warmed beforehand it is only half as quick as the radiant-heat cradle in raising the body temperature. On the other hand, it occupies little space and is almost foolproof.

Our thanks are due to Prof. L. J. Witts for his continued interest in this work.

## ACUTE NICOTINIC ACID DEFICIENCY (ANIACINOSIS)

BY

**B. GOTTLEE, M.D., M.R.C.P.**

Senior Resident Physician, St. Alfege's Hospital (L.C.C.)

General physicians are occasionally confronted with cases of mental confusion or stupor in middle-aged or elderly persons for which no obvious cause is found. A provisional diagnosis of uraemia, arteriosclerotic dementia, or cerebral vascular accident is made and sedatives are administered. Some cases are transferred to mental observation wards. Death usually occurs in a few days as a result of bronchopneumonia, and post-mortem examination may show no cause for their mental state. I believe that an appreciable number of lives could be saved if nicotinic acid (niacin) therapy was instituted rapidly in these patients. The following is a brief description of five such cases.

#### Case I

A woman aged 56 was admitted to Highgate Hospital (L.C.C.) on March 7, 1942, in alcoholic coma. She was cyanosed, with the pulse imperceptible. Following warmth, oxygen, and 4 c.cm. of nikethamide (diethyl nicotinamide) she revived. On March 8 she was quite well, apart from some amnesia for recent events. On the 10th she became confused, restless, and irrational, and declined all her food. Her confusion gradually became worse, and on the 11th she was completely disorientated as to time and space, wandering about the ward and talking loudly. Transfer to the mental observa-

tion ward had to be considered. Apart from nystagmus no physical abnormality was noted. 100 mg. of sodium nicotinate and 25 mg. of thiamin were given intravenously. A few hours later she was quieter and less confused. Subsequently she was given daily 200 mg. of sodium nicotinate intravenously, 100 mg. of nicotinic acid or 25 mg. of thiamin. After a total dosage of 400 mg. of nicotinic acid in 28 hours she was greatly improved. She was well orientated as to time and space, and quiet and co-operative, remaining so until her discharge on April 2, 1942. Two months later, when seen as an out-patient, she had no recurrence of mental symptoms and was perfectly well. She was a heavy drinker, mostly of beer, and her diet consisted mainly of white bread, butter, and tea, and some boiled vegetables. She hardly tasted meat. Her gastric juice showed complete achlorhydria. Her blood W.R. was negative. Electrocardiograms revealed left ventricular preponderance but no other abnormality.

#### Case II

This patient, a woman aged 76, was admitted to St. Alfege's Hospital on March 12, 1943, in a state of mental confusion, disorientation, restlessness, and frothing at the mouth. She was incontinent of urine and faeces. The mental symptoms had developed gradually during the past week. She was markedly anaemic, with petechiae and purpura over the whole body and large bruises on both legs. The blood count showed R.B.C. 1,000,000, C.I. 1.4, granulocytes 2,100. Her diet had consisted almost entirely of bread, margarine, and tea for the past few months. She was almost totally blind owing to bilateral cataracts, and her aged husband was a chronic invalid, hence the difficulty of obtaining a suitable diet. She was considered to be suffering from nicotinic acid deficiency, scurvy, and pernicious anaemia. As she was seriously ill, nicotinic acid, ascorbic acid, and liver injections were immediately given. Following 300 mg. of nicotinic acid by mouth in 24 hours her mental state had improved dramatically. She was conscious, rational, and co-operative, and the control of her sphincters was satisfactory. She was still disorientated as to time. After a total dosage of 600 mg. of nicotinic acid by mouth in 48 hours she was mentally clear, and remained so until her discharge from hospital on May 17. The petechiae and bruises disappeared within a week after 1,500 mg. of ascorbic acid injections had been given. The anaemia responded satisfactorily to liver therapy.

#### Case III

A man aged 46, a publican and a heavy drinker of rum and beer, was admitted to St. Alfege's Hospital on June 7, 1943, with ischio-rectal abscess. He was mentally normal on admission. Owing to chronic alcoholism his diet had always been erratic. Four years previously he had had a sore tongue, with cracks which took many months to heal. Since June 2, when the abscess developed, he had had almost no food apart from alcohol. On June 7 the abscess was incised under spinal anaesthesia. Twelve hours after the operation he became delusional and hallucinated, but had insight into his condition. He was worse at night, when he was noisy and disturbed. He was transferred to the mental observation ward and considered. When seen by me on June 10 he was confused and completely disorientated to time, but was aware of his confusion. His mouth and tongue were fiery red and dry, but no other physical abnormality was noted. Although he was subsequently unaware of this examination he was able some days later to give a vivid description of his delusions and hallucinations. After a total dosage of 600 mg. of nicotinic acid by mouth in 36 hours his mental state, as well as his tongue, became normal, and remained so until his discharge from hospital on June 21. When seen one month later as an out-patient he was perfectly well. The gastric juice showed hypochlorhydria. The blood W.R. was negative and the blood urea normal.

#### Case IV

A woman aged 62 was admitted to St. Alfege's on Sept. 16, 1943, in a state of mental confusion and disorientation. She had always been a small eater, and, according to her husband, "picked at her food like a baby." Since the death of her son a year ago her appetite had become even worse; but, apart from chronic constipation, her general health remained fairly good. Following some mental shock a month before admission, she became listless and could only be persuaded to take bread soaked in milk. There was no history of alcoholism. The angles of her lips became cracked three months previously. Her memory began to fail two weeks before admission and she was confused and disorientated, with incontinence of urine. Her tongue was sore for 10 days. Her symptoms grew progressively worse. She was given orally 90 mg. of thiamin and 150 mg. of nicotinic acid daily from the time of her admission until Sept. 27, without improvement.

When I first saw her on Sept. 27 she was confused and disorientated to time and space. She was incontinent of urine, and her memory, especially for recent events, was grossly impaired. She was a small thin woman, with an inelastic and dehydrated skin. Her nose was red and the backs of her hands were smooth and

shiny. The tongue was red, angry-looking, and completely deficient of papillae. Her lips were swollen and inflamed with fissures at both angles (she had worn no dentures for 12 months). There was bilateral blepharitis, with purulent conjunctival discharge, and she had obvious bilateral circumcorneal injection but no corneal ulcers. There was no evidence of nystagmus or peripheral neuropathy. Investigations resulted as follows: Blood W.R., negative; C.S.F., normal; blood urea, 42 mg. per 100 c.cm.; blood count, normal. A test meal on Oct. 29 showed the presence of free HCl in normal amounts. The barium test meal was normal.

The mental symptoms considered relevant were followed up according to the routine mentioned by Sydenstricker and Cleckley (1941). Nicotinic acid orally had no effect on her illness, but response was rapid after intramuscular injection of nicotinic acid. The lips as well as the tongue improved with nicotinic acid, but riboflavin was necessary before the fissure on the right commissure healed satisfactorily. On Nov. 25 she was discharged perfectly well apart from a mild cystitis, the result of repeated catheterization. In this patient, although other evidences of pellagra were present, the mental symptoms were predominant.

#### Case V

A woman aged 71 was admitted to St. Alfege's on Oct. 22, 1943, with a large, painful, malignant ovarian cyst. This was removed on Oct. 23 under N<sub>2</sub>O-oxygen-ether. Thirty-six hours later she became confused and restless, and attempted to get out of bed. When seen on Oct. 26 she was completely confused and disorientated to time and space, and memory was grossly impaired. She had bilateral conjunctival discharge, with circumcorneal injection but without corneal ulcers. No other evidence of nutritional deficiency or of C.N.S. or cardiovascular changes was noted. The tongue was dry and furrowed. Owing to her illness she developed anorexia, and her diet was grossly deficient for some months before admission. She was given daily 600 mg. of nicotinic acid orally, 1/2 oz. of marmite, and milk up to 2 pints. After receiving 600 mg. of nicotinic acid a marked improvement in her mental state resulted, and after 1,200 mg. in 48 hours her mental state became normal and remained so until her discharge from hospital three months later, despite complications of bronchopneumonia and cystitis.

#### Cases in the Literature

It is now generally recognized that the mental as well as the skin and most alimentary-tract lesions of pellagra are relieved by nicotinic acid. Hardwick (1943) recently described 12 such cases seen in Britain in a mental hospital and a mental observation ward. Cleckley *et al.* (1939) described cases of stupor with little or no evidence of pellagra which improved rapidly after nicotinic acid therapy. Jolliffe *et al.* (1940) described a syndrome in chronic alcoholics which they named nicotinic acid encephalopathy. The symptoms were clouding of consciousness, cogwheel rigidities, and uncontrollable grasping and sucking reflexes. Rapid recovery followed nicotinic acid therapy. Sydenstricker and Cleckley (1941) described cases with diverse symptoms of stupor, manic excitement, delusions, hallucinations, and disorientation: these cases showed no other evidences of pellagra, but responded rapidly to nicotinic acid. Sydenstricker (1943) suggested that the three latter groups of cases, as well as Wernicke's encephalopathy, are examples of acute nicotinic acid deficiency, of which that of Jolliffe *et al.* is the most acute and complete. Sydenstricker postulated that these cases have marked functional disturbances but show no anatomical changes, whereas pellagra is due to chronic partial nicotinic acid deficiency and anatomical changes are present. Nicotinic acid takes part in the formation of coenzymes 1 and 2, which are concerned in cellular respiration and possibly carbohydrate metabolism. Thus acute nicotinic acid deficiency may result in marked functional disturbances of the brain, since that organ has a high and more urgent requirement of oxygen and carbohydrate than other tissues.

Although pellagra itself is rare in Britain (Kinnier Wilson, 1940) it is likely that acute nicotinic acid deficiency may be more frequent. These cases are most likely to be seen in municipal hospitals or mental observation wards. As I was able to find reference to only one such case in Britain—by Slater (1942)—a brief description of the clinical features of this condition will not be out of place here.

#### Aetiology of Aniacinosis

(1) Elderly people living alone and in poor circumstances find wartime shopping especially difficult. Their diet is thus unlikely to contain fish, meat—particularly liver—and dried

eggs, which are important sources of nicotinic acid at the present time among the general population. After an acute infection, such as pneumonia, or an operation, they are likely to obtain a diet consisting of carbohydrates and fluids only: acute nicotinic acid deficiency may thus occur. (2) Chronic alcoholism due to: (a) anorexia; (b) associated gastritis and achlorhydria, which (c) may interfere with the absorption of the vitamin, nicotinic acid, which is needed for the metabolism of alcohol in the brain, as shown by Devan (1943). (3) Gastro-intestinal disturbances such as ulcerative colitis and dyspepsias, organic and functional, with restricted diets and interference with absorption of the vitamins.

#### Diagnosis

Any of the following symptoms—mental confusion, delusions, hallucinations, stupor, manic excitement, confabulation—or those of nicotinic acid encephalopathy may occur (Jolliffe *et al.*, 1940). Pellagra, thiamin deficiency, ophthalmoplegia, or other vitamin-deficiency diseases such as scurvy, as in Case II, may be present. In the majority of cases, however, no other evidences of vitamin deficiency are found. The fiery-red so-called "toxic tongue" without loss of papillae may be noted in some, as in Case III. The mental symptoms are likely to become progressively worse after parenteral glucose-saline and sedatives, the usual treatment in these cases. Some cases may be transferred to mental observation wards. Death is likely to occur in 4 to 5 days, with bronchopneumonia as the terminal event.

Uræmia, cerebrovascular accidents, arteriosclerotic dementia, frontal-lobe tumour, bromide intoxication, and neurosyphilis would have to be excluded. In cases of doubt, however, nicotinic acid should immediately be given in the large doses recommended by Sydenstricker. Important points in diagnosis are: (1) dietary history; (2) possible history of chronic alcoholism; (3) response to treatment with nicotinic acid, which usually effects dramatic improvement in 1 to 2 days. It may be mentioned here that nicotinic acid had no effect on four cases of advanced arteriosclerotic dementia treated in chronic hospital wards on the lines suggested by Sydenstricker.

#### Treatment

1. Sydenstricker suggested 100 mg. of nicotinic acid or 30 mg. of nicotinamide hourly for 10 doses in the first two days by mouth or by stomach-tube. In stupor or noncooperative cases sodium nicotinate in 100-mg. doses may be administered intravenously or intramuscularly. After two days 500 mg. of nicotinic acid daily for a few more days in 5 doses, then a residual dose of 25 mg. t.i.d. (Nicotinamide should be prescribed in cases in which vasodilatory symptoms are excessively uncomfortable.) It is likely that half the above dosage would be adequate in most cases. In encephalopathy and comatose or stuporous cases the full dosage should be given.

2. Marmite 1/2 oz. or bemax 1 to 2 oz. daily.

3. Thiamin in 25-mg. doses daily, particularly with associated neuropathy or ophthalmoplegia.

4. As soon as possible a good mixed diet, including fish, meat, liver, milk, and vegetables.

#### Summary

Five cases of acute nicotinic acid deficiency are described.

The clinical picture of this condition is discussed.

It is considered that in doubtful cases nicotinic acid therapy should be immediately tried.

My thanks are due to Dr. W. W. Sargant and Dr. E. Slater for their helpful suggestions; to Dr. S. Alexander for the notes on Case I, and to Dr. B. A. Young, medical superintendent, St. Alfege's Hospital, for permission to publish Cases II-V.

CHEST SCREENING IN THE ANTE-NATAL  
CLINIC

BY

RACHEL FRANK, M.D. Prague

Assistant Medical Officer to the Maternity Department, Paddington  
Hospital (L.C.C.)

AND

A. L. JACOBS, M.R.C.P.

Senior Resident Physician, Paddington Hospital

At the beginning of 1943 it was decided to institute a screen examination of the chest for all women attending the ante-natal department of Paddington Hospital, as part of the routine general examination which they undergo. This was organized by the maternity department and the medical department in co-operation, with the help of the radiographic staff.

## The Procedure

At her first attendance in the ante-natal department each expectant mother is given an appointment in the following week, and it was found that a single weekly screening session of 30 to 45 minutes enables the work to be covered without difficulty. With very few exceptions the mothers much appreciate this service and attend punctually, so that organization has been easy and has made very little demand on the hospital staff. The screening has always been done by the same person, and our practice has been to order full-size films in all cases where the screen examination reveals any abnormality of importance. For this purpose calcified foci have been included only when extensive, multiple, or accompanied by other shadows—the common small and compact Ghon focus or calcified gland focus being "passed" on the screen examination alone.

The scheme has now been in operation for a year, with an average weekly attendance of 20 to 30 women. We publish the following summary of the results as an indication of the possibilities of the method.

Total number screened in 1943 .. .. .	1,125
Total number of films ordered .. .. .	63
Findings in the films:	
No abnormality .. .. .	22
Active tuberculosis .. .. .	6
Pleural effusion .. .. .	1
Unilateral phthisis .. .. .	1
Bilateral phthisis .. .. .	4
Possibly active tuberculosis .. .. .	2
Probably inactive tuberculosis or doubtful tuberculosis .. .. .	9
Calcification shadows .. .. .	11
Non-tuberculous changes:	
Increased vascular shadows, general .. .. .	6
Increased vascular shadows, local .. .. .	2
Pleural or pleuro-pericardial adhesions .. .. .	2
Miscellaneous .. .. .	3
? Benign pleural neoplasm .. .. .	1
Partial collapse, ? cause .. .. .	1
Anatomical anomaly of ribs .. .. .	1
Approx percentages of tuberculous disease out of total screened:	
Active, requiring immediate admission .. .. .	0.5%
Possibly active, requiring close observation .. .. .	0.2%
Probably inactive or not definitely tuberculous, but requiring observation .. .. .	0.8%

For comparison with these figures we may take the findings in a group of women of roughly comparable age reported by Clive (1943). These were W.A.A.F. personnel, a group of 30,000, ages 17½ to 45, examined by miniature radiography. Clive found that 0.4% required immediate institutional treatment for tuberculosis and 0.6% required observation, of whom 0.2% were later found to need institutional treatment. Our figures appear to be very similar to these.

## Comment

The principle of mass investigation—searching for cases of tuberculosis among the apparently healthy—which has been quite extensively employed in some other countries since the last war, is gaining increasing adherence in this country. So far it has largely been confined to special groups of the population, such as nurses and medical students, who appear to be particularly exposed to the risk of tuberculosis, or those whose health is of special importance and who are organized in groups which make investigation relatively easy—e.g., Service

personnel. We think it is clear that pregnant women fall into the latter category, if not into the former, and the use of x rays in their supervision is both highly desirable and easily practicable. While we are prepared to agree at once that the most suitable method of mass investigation is by miniature radiography, we think that until apparatus for this becomes universally available (which is likely to be a considerable time) the possibilities of screen examination are by no means to be despised. It is clear that this method will reveal a number of cases of unsuspected tuberculosis comparable with, if not fully equal to, that found by miniature radiography, and it has the very great advantage of universal availability. Nearly every general hospital which does ante-natal work has a screen apparatus, and a simple system of collaboration between local authorities and hospitals, both voluntary and municipal, would make it possible to examine also those women who attend ante-natal clinics conducted outside the hospitals. In this way a very large proportion of the expectant mothers in the country could be brought under immediate observation. The method is quite economical, for films are needed only in about 5% of all women screened, and some further experience will probably enable the number of "unnecessary" films to be still further reduced.

In this brief note we have confined our attention to pulmonary disease, but screen examination also has its value for the assessment of cases of heart-disease, and draws attention to a certain number of cases which have been overlooked in the physical examination.

## Summary

Screen examination of the chest has been included in the general examination of all women attending the ante-natal department of a general hospital. Organization was found to be easy.

Figures are given of the number of cases of pulmonary disease discovered by this method.

Our thanks are due to Mr. A. R. Hayward, senior radiographer, and Auxiliary Nurse E. A. Gale for their help in organizing this work.

## Medical Memoranda

Intussusception of Small Gut due to  
Foreign Body

Intussusception of the small gut is an uncommon occurrence, and the following case illustrates points of interest.

A young man 19 years of age, employed as an electrician, was admitted to the Pembroke County War Memorial Hospital on the evening of Oct. 21, 1943. He complained of some abdominal pain, but this was not stressed, and pain obviously was not a prominent feature. The history given was that after starting to eat his lunch, soon after midday, he was suddenly seized with severe abdominal pain, distributed to the umbilical region, accompanied by vomiting. He walked to the surgery of the medical officer, and was ultimately sent to hospital. On admission his general condition was satisfactory, and he made little complaint except for the occurrence of several bouts of vomiting. His temperature was 99.8°; the bowels were opened that morning.

Examination showed the presence of a smooth circular mass, slightly tender, of ill-defined edges, and situated on the right side a little below the umbilicus; it was movable transversely. The abdomen was opened that night by Mr. A. B. Davies. Dilated small gut presented in the wound, and the lower right abdomen was occupied by a curved intussusception about 8 in. long and situated about 12 in. from the ileo-caecal juncture. Attempts at reduction failed, and resection of gut with end-to-end anastomoses was carried out. Convalescence was uneventful. Subsequent examination of the removed gut showed the invaginating portion to be gangrenous, while one half of a steel screw occupied the lumen of the bowel at the apex of the intussusception.

The absence of urgency in clinical findings of this case contrasted with the gangrenous state of the gut in the intussusception. The swallowing of the steel screw which initiated the condition probably resulted from the habit of technicians of using the mouth as a temporary receptacle for such objects during their mechanical operations.

## Reviews

### THE EXTRA PHARMACOPOEIA, VOL. II

*The Extra Pharmacopoeia*; Martindale. Twenty-second edition, Volume II. (Pp. 1,217. 27s. 6d.) London: The Pharmaceutical Press, 1943.

Volume II of the 22nd edition of the *Extra Pharmacopoeia* has now appeared. This completes the second of the editions which have been prepared by Mr. C. E. Corfield and his assistants for the Pharmaceutical Society. It was a matter for great satisfaction when the Pharmaceutical Society took responsibility for the *Extra Pharmacopoeia*, but that is a responsibility which we hope is giving it a headache. It is to be feared that so long as many copies are sold the Pharmaceutical Society will be satisfied that all is well. All is not well. To say this is not to cast any reflection on Mr. Corfield. If a pharmacologist were to write a reference book on chemistry, Mr. Corfield would be the first to pat him on the back and say, "Well, poor chap, he did his best, but what does a pharmacologist know about chemistry?" Nevertheless a chemist, with no pharmacological adviser at his elbow, prepares the *Extra Pharmacopoeia*, a book dealing largely with new drugs and recent advances in medicine. It is not enough to refer special subjects to medical men. At the end of the preface there is a list of medical men from whom advice on certain sections has been obtained. These no doubt give excellent advice in their own line, but they do not help the editor-in-chief to take that balanced view of the whole field which only a person whose principal work in life is a knowledge of the action of drugs and their uses can enable him to take. It is surely the duty of the Pharmaceutical Society to find such a person to be at least co-editor of the *Extra Pharmacopoeia*.

The Society displayed a progressive spirit in 1926 when it founded *Pharmacological Laboratories*. It still maintains these laboratories, but there is an astonishing lack of connexion between them and the Society's publications. There has been little evidence in the *British Pharmaceutical Codex* of 1934 or in the two editions of the *Extra Pharmacopoeia* that these works have had the benefit of that kind of pharmacological advice which can only be given by those engaged in or trained in research. In what way does the book suffer under the present arrangements? It suffers because it includes a mass of data which is probably of no interest to anyone. For example, when Volume II was opened by chance, page 163 appeared. This page contains a detailed account (in very small print) of the determination of rotenone in derris. Now, who is interested in this? It may be that the *Extra Pharmacopoeia* is aiming at the whole world. It may hope to catch the analytical chemists as well as the doctors. For, of course, the analytical chemists are glad to know how to determine rotenone, particularly if Mr. Corfield is so obliging as to tell them how they can really do it. Surely, however, this is too much. The congestion is now too great. The Pharmaceutical Society should no longer tolerate this jumble of pharmacognostical information and analytical methods on the one hand with new drugs and advances in medicine on the other. They have two volumes. Cannot the one volume be used for the one, and the second for the other? Cutting down, however, there must be. The small print makes the book something which many will avoid. It can no longer be carried in the pocket, so why not make it larger and as easy to read, say, as *New and Non-Official Remedies*?

The analytical parts and laboratory methods are done well. The new drugs and uses are done less well. There are strange omissions. Pethidine is not mentioned in spite of a paper on this substance in the Society's own journal in 1940 (*Quart. J. Pharm. Pharmacol.* 13, 318). Pethidine is an important drug capable of relieving pain in those who cannot tolerate any of the opium alkaloids or heroin because these produce nausea and vomiting. Neither is there any mention of thiourea or thiouracil, the compounds now used for thyrotoxicosis. These are serious points which ought to persuade the Society to look for a competent adviser who can speak with authority as co-editor on matters medical. It is granted that there are very few to be found.

The Pharmaceutical Society, by its publications the *Codex*, the *Extra Pharmacopoeia*, and the *Quarterly Journal*, performs a valuable public service. To point out defects in these, and the need for improvements, is not to belittle this service, but is to indicate how this well-disposed Society, which we all respect, can make itself still more useful.

### ACUTE MEDIASTINITIS

*Acute Infections of the Mediastinum*. By Harold Neuhof, M.D., D.S., F.A.C.S., and Edward E. Jernegan, M.D., D.S., F.A.C.S. (Pp. 407; illustrated. 33s.) London: Baillière, Tindall and Cox, 1943.

It is fortunate that acute mediastinitis is not a very common disease, and therefore this volume, which contains detailed records of 100 personal examples of the condition, is of great interest. Neuhof's work on lung abscess is already well known, and any publication by him demands serious consideration.

After surveying the literature, the authors describe their cases, which they divide into four groups: those secondary to trauma of the oesophagus, those preceded by upper respiratory infections, those following infection of the lung or pleura, and finally those of miscellaneous aetiology. In no less than one-fifth of all the examples mediastinitis was due to trauma by instruments passed into the oesophagus—a warning to those who embark upon this form of endoscopy. However, the most common cause of acute mediastinitis was an upper respiratory infection, such as a retropharyngeal or cervical abscess. The surgical anatomy and pathology and the clinical features are discussed in great detail. The radiological diagnosis of the various forms of mediastinitis is well described and illustrated, and the treatment, both conservative and surgical, is considered at length. The authors state that a diagnosis of perforation of the oesophagus is an indication for immediate operation, but in other cases the presence of an abscess should be established, if possible, before drainage is undertaken.

Owing to the rapidity with which spread occurs in mediastinal infections, they will always carry a high mortality, and one object of this book is to draw attention to the circumstances likely to produce an acute mediastinitis, in order that they may be avoided. The book will be of particular interest to those who specialize in thoracic diseases, and it should be read by all who practise oesophagoscopy and gastroscopy. It is unfortunate that a certain lack of dogmatism, particularly in the sections on treatment, lessens the practical value of this interesting work.

### EMERGENCY SURGERY

*Emergency Surgery*. By Hamilton Bailey, F.R.C.S. Fifth edition. (Pp. 969; with 1,039 illustrations (some coloured). 75s.) Bristol: John Wright and Sons, 1944.

Like the book on clinical signs by the same author this may be described as a medical best seller. The new edition is a triumph of patience and perseverance on his own part and that of his publishers, for not only were the original type and blocks destroyed by enemy bombing, but this printing again suffered air-raid damage when it was nearing completion. All branches of surgery are covered, including specialties such as ophthalmology, oto-rhino-laryngology, and gynaecology, but details of fracture treatment beyond the principles applicable to compound fractures are not included. The chapter on the eye is written by Mr. Eugene Wolfe; those on the ear, nose, and throat are by Mr. E. Watson-Williams. These are excellent contributions, which make good reading and blend well with the remainder of the text.

The book as a whole is reminiscent of Lejar's *Urgent Surgery*, for which some years ago we had a great regard and to the author of which Mr. Hamilton Bailey pays tribute. We should like to see the vertical incision for draining a thoracic empyema recommended and illustrated, but our chief differences of opinion with the author are in the section on head injuries, notably with the view that the unconscious patient should be laid flat in bed, that compound fissured fractures of the skull should be left alone unless physical signs are present, and that extradural haemorrhage is often bilateral. The tourniquet illustrated on page 563 is in our opinion futile, and it is better to arrest haemorrhage from scalp wounds by putting haemostats, not as advised on the whole thickness of the scalp, but on the

cut edge of the galea aponeurotica, which is then retracted towards the wound edge. Nor can we agree with the statement that dehydration should not be practised for 48 hours after a head injury; it is at this period that its effects are so often needed to limit brain swelling and check oedema. These criticisms, however, merely emphasize our high regard for the book as a whole. An appendix contains some useful addenda culled from recent papers, and thereby adds to the value of this edition by bringing it thoroughly up to date.

### MEDICAL LIBRARIANSHIP

*A Handbook of Medical Library Practice.* Edited by Janet Doe. (Pp. 610. \$5.00 or 30s.) Chicago: University of Chicago Press; London: Cambridge University Press.

The American Library Association has performed a valuable service to all librarians and those who use medical libraries by publishing *A Handbook of Medical Library Practice*. The book is comprehensive and covers the whole subject in an admirable manner. The first chapter deals with development, distribution, and administration, with appendices showing libraries which possess over 100,000 volumes, and libraries outside North America listed under countries. This is followed by chapters on periodical and book selection and ordering, cataloguing, subject headings, classification, pamphlets and pictures, maps and microfilms, rare books and the history of medicine, and reference works, including an annotated list.

The question of classification is always of interest, and the various methods now in use are adequately expounded. An over-elaborate classification hinders rather than helps the reader. The aim should be to provide a simple but efficient means of locating books or journals on a given subject. The chapter on rare books and the history of medicine has an appendix in which are listed bibliographies, biographies, and general histories, by localities and subjects—a very instructive and useful chapter. The final chapter, on works of reference, is interesting and informative, and gives an annotated list of reference books. To sum up, the whole material is excellent, and the editor and her colleagues deserve all praise for producing this long-wanted volume.

### Notes on Books

*The Unfit made Fit* (Longmans, Green and Co.; 1s.) is the fourth in a series of illustrated booklets produced by the British Council under the general title "Britain Advances," in which Dr. HAROLD BALME has written an up-to-date account of rehabilitation in the medical sense of the word. Modern methods and developments in this field are described in a way understandable to the general reader, and there are many good photographs illustrating the text.

As is intimated in its title, *Venereal Diseases*, by A. CAMERON EWING, in E. and S. Livingstone's Catechism Series consists mainly of question and answer. The questions are for the most part well chosen and the answers accurate and sufficiently full for the student or general practitioner. There are a few points which call for criticism: (1) The uninitiated might think from para. 4 of page 26 that congenital syphilis could arise from an infected father without the mother having suffered from the disease. (2) The section on the Wassermann reaction is most inaccurate. Complement is not generally considered part of the haemolytic system, and in the account of the test proper no antigen (extract) is included. (3) Iodides are prescribed for early syphilis on page 43 and stated to be "probably of no use" on page 50. (4) More might have been said about false-positive serum reactions in suspected syphilis, and the same applies to the use of cultures in gonorrhoea, especially in tests of cure of the female. With the above reservations, this little book (price 1s. 6d.) can be confidently recommended; Major Ewing has had a very considerable experience of his subject and has made his points with care and lucidity.

*A New Conception of Keratoconjunctivitis Sicca (Keratitis Filiformis in Hypofunction of the Lachrymal Glands)*, by HENRIK SJÖGREN, is published in Sydney at 25s. by the Australasian Medical Publishing Company. In 1933 Sjögren in a supplement to the *Acta Ophthalmologica* (Supplement II) gave an excellent survey of the scattered ophthalmic and general literature on the association of unusual conjunctival and corneal reactions with xerostomia and polyarthritis. This material, together with his own clinical and histological observations, fully established keratoconjunctivitis sicca as an independent and by no means rare clinical entity. Sjögren and others have since expanded our knowledge of the syndrome, which is now generally known after him, and the fullest account available in English was contributed by Sjögren in 1940 to Ridley

and Sorsby's *Modern Trends in Ophthalmology*. Dr. J. Bruce Hamilton of Hobart, Tasmania, rightly considered Sjögren's monograph, published in German, to be worthy of an English translation, and he has carried out his task well. The numerous photomicrographs have been well reproduced, though they lack the sharp definition seen in the original publication. The selected list of references given by Dr. Hamilton in a foreword and his own postscript help materially to bring the monograph up to date.

*A Mixed Bag: Recollections and Reflections of a Surgeon*, by W. BERNARD SECRETAN, M.B., F.R.C.S., is an unpretentious account of the busy and happy life of one who settled in Reading as a partner in general practice, became specially interested in surgery, and eventually devoted himself entirely to it. The author was attached to the Royal Berkshire Hospital and shows a justifiable pride in his recollections of it, for during his time the hospital developed greatly in size and in scope. Mr. Secretan's social interests have also been wide and his recreations have ranged from hunting to sketching, not forgetting motoring, in the earlier stages of which he took a very active part. The book is well illustrated by photographs, several of which were taken in various parts of the world when the author, soon after qualification, made two extensive voyages as ship surgeon—a course which he cordially recommends to young doctors before they settle down in practice. The book will be of considerable interest to the author's many friends, and it can be recommended to any who would like to follow the developments of medical practice during the past forty years. It is published at Reading by the Crown Press, Caxton Street, at 6s.

## Preparations and Appliances

### AN INTERCOSTAL DRAIN

Dr. JAMES PHILP writes from the Mayday Hospital, Thornton Heath:

The type of intercostal drain described and illustrated below has been designed by Mr. Peter Ayres of St. Mary's Hospital and used with success.

It consists of an intercostal tube fitted with an obturator. The tube is bevelled off at one end in order to form a complete curve with the end of the obturator, and is held in position by a metal disk which lies against the chest wall. The disk has a rectangular aperture in the centre, through which the tube passes, two sides of the aperture fitting into slots in the tube,

which pass into, but not through, the tube wall and therefore do not occlude the lumen of the tube. The disk is held in position on the chest wall by two small strips of elastoplast.

The advantages of this tube appear to be: (1) With the obturator in position, a rounded end is formed which facilitates introduction. (2) Should the tube become blocked, it can easily be cleared by inserting the obturator. (3) The disk holds the tube securely and obviates the possibility of its slipping out of position; it has also been found to be more comfortable than the usual method of securing by a safety-pin.

Mr. Ayres would like to thank Mr. F. Swinton, M.D., F.R.C.S., medical superintendent of Mayday Hospital, Croydon, for his help and advice; also Messrs. Down Bros., who make the tube.

Burroughs Wellcome and Co. have published an annotated review of the properties and uses of pethidine hydrochloride, the synthetic analgesic and antispasmodic drug, which has recently been the subject of extensive clinical studies. Copies of this pamphlet are available to members of the medical and allied professions on application to Burroughs Wellcome and Co., 12, Red Lion Square, London, W.C.1.

## BRITISH MEDICAL JOURNAL

- LONDON

SATURDAY MARCH 18 1944

## CHEMOTHERAPY AND PNEUMONIA

The successful clinical trials with sulphapyridine in the treatment of lobar pneumonia reported by Evans and Gaisford<sup>1</sup> were followed by confirmatory reports from workers in different parts of the world. In their original work Evans and Gaisford observed a case mortality of 27% in a hundred cases of lobar pneumonia of mixed type, against 27% in an equal number of controls, of similar age and sex, given non-specific treatment. In a later paper Gaisford<sup>2</sup> reported a fatality rate of 6.5% in a hospital which in the preceding years had had a rate of 22%. Although lower case mortalities than these have been recorded by some observers, the available evidence suggests that as a result of the introduction of chemotherapy the case fatality rates of cases treated in hospital have been reduced to about a third of the previous level. The simplicity of administration of sulphonamide drugs suggests that just as favourable results could be obtained at home as in hospital. That this can be achieved was demonstrated by Rosenthal, MacCall, and Pratt,<sup>3</sup> who found a case fatality rate of 3.8% in 132 cases treated at home with sulphathiazole. These sensational results in the control of pneumonia have tended to overshadow the importance of this disease, which still remains a major problem in public health: over 76,000 deaths were attributed to this cause during 1940-2 in England and Wales. The effect of the new therapy on the mortality of the whole population cannot be precisely determined. The lack of knowledge of the number of cases and the fluctuating trend of the disease permits of only an approximation of the improvement, which W. J. Martin<sup>4</sup> estimated to be of the order of 10%—considerably below that found in hospital experience. A possible explanation is that the age constitution of hospital patients is different from the general population. T. Anderson<sup>5</sup> produced evidence that sulphonamides are less effective at the extremes of life. He showed, from the notifications and deaths of the City of Glasgow, that the improvement under 1 year of age and at ages 45 and over was considerably less than at other ages, and the poorer results obtained at the extremes of life masked the large improvement in the middle age groups. The ratio of deaths to notifications for 1939-41 as a percentage of 1922-38 was 70.5 for all ages, while for ages 1-10, 10-20, 20-45 it was 46.2, 35.3, and 42.3.

It is very difficult to obtain extensive and reliable morbidity data in Britain, but in the United States the position appears to be somewhat easier. Ungerleider, Steinhaus, and Gubner,<sup>6</sup> making use of the records of the Equitable Life

Assurance Society of the United States, have examined the present trend of pneumonia compared with that of the recent pre-sulphonamide period. Their data consisted of the records of the employees of large industrial organizations who were insured for health and life under a group policy. These numbered over 100,000 and covered the period of working life; 62% were in the age groups 25-44. The incidence of pneumonia had increased during the later part of the period covered, from 2.52 per 1,000 in 1937 to 3.18 in 1941. The mortality was 54.7 per 100,000 during 1935-8 and 11.9 for the period 1939 to June, 1942. This fall was very much larger than in the general population; the death rate in New York City declined by less than 50% from 83 in 1935-8 to 45.3 in 1940-1. The more favourable age constitution of the industrial group, which excluded the very young and old ages, was responsible for the difference. The measure of benefit resulting from chemotherapy was larger than the death rates indicated, since the case mortality among the industrial workers fell from 20.8% in the first period to 3.9% in the second. Not only has mortality been reduced but the course of the disease has also been shortened by the modern treatment: during the first period the average duration of non-fatal pneumonia illness was 43 days, and during the second 36 days.

## HYGIENE, MORALE, AND DESERT VICTORY

The conditions that obtained in the Western Desert were so local and exceptional that much of the knowledge that can be distilled from the experiences of the Eighth Army therein cannot be applied directly in plans for military enterprises elsewhere. Nevertheless the Middle East campaign, and especially the Battle of El Alamein, are well worthy of deep study by military scholars, and offer much of real value to such as are concerned with or interested in military medicine. To the latter the thoughtful article by Lieut.-Col. H. S. Gear appearing in this issue will serve as a useful introduction, for in it most of the hygiene lessons are clearly displayed.

The fluctuating excursions of the Eighth Army and the Afrika Korps to and fro across Cyrenaica had ended in the summer of 1942 on the Alamein line. The Eighth at this time was composed of pitiless men soaked in war, fully trained and experienced, but dispirited. To it this rhythmical rushing forwards and backwards seemed to contain no promise of finality. It was no longer a European but a Desert Army, with its own cultivated and characteristic attitudes and habits. It was an Imperial and not a British Army, and partly for this reason was the finest and most finished instrument of war thus far fashioned by the Allies. Because of its peculiar constitution and unusual experience it needed an exceptional commander if its qualities were to be most advantageously exercised. For this position General Montgomery was chosen. In him this somewhat arrogant and truculent amalgam of Imperial types secured exactly what it needed. Here was an outstanding student of military affairs with a long and sound record, an ascetic flamboyant martinet, an eager fighter with a fierce faith in himself. Strongly reinforced and abundantly equipped with guns and aircraft from

home and with aircraft and tanks from America, the Eighth quickly accepted its picturesque and unconventional General and came to share his opinion that it was an independent and invincible formation engaged in a more or less private crusade. These are matters of great medical interest, since it is a well-established fact that there is an inverse relation between the level of the morale and of the training and experience of a formation on the one hand and the incidence of sickness and of battle casualties on the other. Much sickness derives directly from low morale, for disability is commonly nothing more than depicted disinclination. The unspoiled desert is a healthy environment, but like all others it can quickly be transformed into a disease-breeding cesspit if occupied by great numbers of human beings untrained in the techniques of establishing between themselves and its novel and ungentle conditions a harmonious relationship. Men experienced in combat are less likely to become casualties than are the raw and uninoculated.

The incidence of sickness among the veterans of the Eighth at this time was remarkably low, as was to be expected, for they felt themselves dedicated to a high purpose; they had faith in themselves and in their leader. The self-reliance of those loose-limbed sun-tanned youths, evoked so skilfully, endowed them with an eager positive desire to be healthy; and healthy they were. Moreover, they had, during the previous two years, become "salted," adapted, and now were able to flourish biologically under the conditions of desert warfare. Not so the reinforcements, for, complete as their education and training had been, they had yet to face the supreme test. They still needed time to make psychological and physiological adjustments. Nevertheless, even among them the incidence of sickness was low, for they were carefully tended by the Medical Services; they knew that they stood on the threshold of great adventure, and that they were being sympathetically watched by an astonishing man who had invited and gained their staunch allegiance and had raised them into a partnership with himself. This low incidence of sickness could have served as a true measure of the prospects of victory. It is among the disinterested, the disillusioned, and the already defeated that sickness rages.

The tactical and medical problems at Alamein differed from those of all other battles on the Western Desert. Here the Wavell plan of striking at the flank on the coast and encircling the other ending on the desert could not be adopted; the enemy line had to be breached by a frontal attack. Furthermore, ideas concerning the combined and integrated action of Air Force and Army and the tactical use of armour had been evolving rapidly, and at Alamein the latest were tested. The forces engaged were numerically more or less equal, but the Eighth was the better equipped. Rommel—General Montgomery's self-chosen personal adversary—was absent, and his deputy was completely deceived concerning our intentions and overwhelmed by General Montgomery's resourcefulness and quick thinking. Montgomery struck at night with guns, aircraft, and infantry. Night after night the breach in the enemy's line was widened and deepened until it was complete. Through it the armour passed far out behind

the enemy infantry, to spread panic among these and to force the enemy armour to give battle. Rommel, returning post-haste, was left with no alternative other than to pull out remnants of his armour and his best mobile units and to race back across Cyrenaica, leaving all the rest behind. The Eighth, always close on his heels, reached El Agheila inside three weeks. It was during this chase that our troops became exposed to grave danger, against which only the Medical Services could hope to protect them. The countryside had been thickly populated with Germans, Italians, and Arabs, and was now rank with pollution. It is understandable that a fast-retreating and defeated army cannot bury its dead. But it is always surprising to find that German soldiery fouls its own nest with a thoroughness that is truly Teutonic. Food scraps abounded everywhere, and so it was that flies in their millions pervaded everything. From these and similar perils the Eighth was safeguarded in the manner described by Col. Gear, and there is much strength in the argument that differences in the quality of the Medical Services of the two armies and in the sanitary habits, personal and public, of our men and of the enemy respectively were largely responsible for the result of the Alamein battle and of the Middle East campaign.

#### TOXAEMIA OF PREGNANCY AND HYPERTENSIVE STATES

Golden, Dexter, and Weiss<sup>1</sup> again call attention to the fact that pregnancy toxæmia is often followed by permanent and progressive vascular and renal damage. Whereas in the past the resultant injury was thought to be chronic glomerular nephritis, workers in America, Germany, and Great Britain have in recent years repeatedly demonstrated that the most constant sequel is hypertension. Some have gone so far as to suggest that glomerular nephritis is never caused by pre-eclampsia and eclampsia, but Golden and his colleagues report that, in addition to hypertension, renal lesions do occur; these are generally nephrosclerosis or chronic vascular nephritis, but a condition indistinguishable from chronic glomerular nephritis is sometimes found. About 25% of women who develop pre-eclampsia or eclampsia are left with permanent vascular disease. Indeed Browne and Dodds,<sup>2</sup> taking an unusually strict standard for normal, put the figure as high as 50%. Toxaemia complicates 6 to 9% of all pregnancies, so that two out of every hundred women who begin pregnancy with a normal blood pressure and renal function develop permanent hypertension. Once a pregnancy complicated by toxæmia is terminated the blood pressure tends to fall and often returns to normal. In some cases, however, it never reaches the pre-pregnancy level, and in others it rises again after a latent period of months or years. The ultimate effect of the toxæmia cannot therefore be judged until one or two years have elapsed. Once established, the vascular disease tends to progress, and, indeed, may assume the form of malignant hypertension. Death from cerebral haemorrhage, cardiac or renal failure is the final outcome. Golden and his colleagues do not agree that an inherited predisposition to hypertension is a factor in the aetiology of pre-eclampsia and eclampsia.

The severity of the toxæmia bears no relation to the incidence of sequels; in fact, vascular damage occurs more frequently after pre-eclampsia than eclampsia. It is the

<sup>1</sup> *Arch. Intern. Med.*, 1943 72, 301.

<sup>2</sup> *J. Obstet. Gynaec. Brit., Emp.*, 1939, 46, 443.

duration of the toxæmia which chiefly determines its after-effects, and even the mildest toxæmia, if allowed to persist for longer than three weeks, is likely to prejudice the future health of the patient. The teaching of most obstetricians—that pregnancy should be terminated if the toxæmia does not clear up completely after three weeks' conservative treatment—is endorsed by Golden's observations. In the present state of knowledge induction of labour without undue delay, even when there is no immediate risk from the toxæmia, would appear to be the only feasible way of trying to prevent the late sequelæ of hypertension and nephrosclerosis.

### VACCINATION AGAINST SMALLPOX

The occurrence of smallpox in a Middlesex hospital is a reminder that only a small minority of us are resistant to this dreadful infection. At present rather less than half the infant population is being vaccinated, and, apart from certain medical and nursing staff and, since the war, men and women in the Services, revaccination is seldom done. As immunity after primary vaccination lasts only for 5 to 7 years, it follows that the bulk of the population is susceptible, so that when a smallpox scare occurs vaccination or revaccination on a wide scale becomes essential. Unfortunately, vaccination in these abnormal circumstances is not always carried out with the care it needs, and many of those who, because their vaccination did not "take," were regarded as immune are in fact still susceptible and are examples of inefficient vaccination. The proper procedure for effective vaccination has recently been set out fully and lucidly in a pamphlet for the instruction of Army medical officers.<sup>1</sup> This has been done because unfortunate incidents have occurred abroad, and too often men who were regarded as insusceptible have on revaccination shown normal "takes." Vaccine lymph after purification is stored at  $-10^{\circ}\text{C}$ . in single-dose capillary tubes, or in ampoules containing 25, 50, or 100 doses. When the lymph is issued the date of issue is written on the label as "date of manufacture," and this lymph can be used up to 14 days after issue if kept at a temperature of  $1^{\circ}$  to  $10^{\circ}\text{C}$ . If refrigeration is not available, the lymph must be used within 7 days of issue. In doing the test the site of inoculation should be cleaned with soap and water and then rubbed with ether or spirit; non-volatile antiseptics (e.g., iodine or mercuric chloride) must not be used. With the skin dry, the lymph is expelled from the capillary tube using a small rubber expeller (obtainable from Baird and Tatlock Ltd.) or the teat of a baby's feeding-bottle. If ampoules are being used for large-scale vaccination, sterilized and cooled Hagedorn needles are dipped in the lymph, 3 or 4 needles being used in rotation to allow proper cooling after sterilization. Scarification is done through the lymph or with the needle freshly dipped in it. Ordinarily a single linear scratch one-quarter inch long is sufficient. The incision is made slowly with the skin taut and only deep enough to cause a slight exudation of the serum without blood; otherwise the lymph may be washed away. In the presence of an outbreak of variola major three well-spaced incisions may be made to give a more solid immunity. It is important that the lymph be allowed to dry before the application of a dressing of sterile, but not antiseptic, gauze kept in place by adhesive strapping. The vaccinated arm should preferably be rested in a sling and should be examined after 2, 4, and 7 days. Three types of reaction are recognized: (1) immediate, where immunity is high, characterized by redness or papules within 8 to 72 hours and fading quickly; (2) vaccinoid or accelerated, where some immunity exists, and the reaction (papules

plus vesicles) reaches its maximum in 3 to 5 days; and (3) the well-known primary vaccinia where immunity is nil. If there is no response by the fourth or fifth day, and immunization is urgent, vaccination may be repeated on the fifth day. If three attempts fail with lymph that has successfully vaccinated others, then, and only then, should the individual be classed as insusceptible. A point that recent Scottish experience has established is that successful vaccination in the incubation period need not give absolute protection against the infection.

An objective test for assessing individual resistance to the smallpox virus would be of great help. An *in vitro* test has, in fact, been described by Nagler,<sup>2</sup> who found that potent vaccinia virus had the same property as influenza virus of agglutinating fowl red cells, and that this property could be neutralized by mixing the virus with antibody-containing serum from rabbit or human. Corroboration of this finding is needed. Meanwhile the practitioner would do well to refresh his memory on the clinical features of smallpox: the influenza-like onset, sometimes with prodromal rash (if petechial or haemorrhagic the outlook is grave); the centrifugal distribution of the rash, which can be properly appreciated only if the patient is completely stripped; and the inexorable march of the lesions in stages, not in crops, from papules through vesicles to pustules.

### HOW TO BREAK OFF ALCOHOL

Some interesting papers have appeared during the last few years<sup>3-5</sup> on a method of curing a taste for drink, and the results show that by its means a considerable number of confirmed heavy drinkers have abstained for periods varying from six months to five years. The number of patients treated was 1,042 by last year.<sup>5</sup> The method makes use of a conditioned reflex. The patient, who must be willing to be cured, attends for four to eight treatments, which may be given over a period of from seven to twenty-eight days. When he comes he is given his favourite drink to which a dose of emetine hydrochloride has been added. The dose is in the neighbourhood of one grain. This leads to nausea; and when this appears a further dose of emetine is injected which causes vomiting in two to eight minutes. By repeating this procedure several times on different occasions the patient then finds that he becomes nauseated and vomits when he takes a drink which does not contain emetine; and even the smell alone causes nausea.

In the first paper, written by W. L. Voegtlin, the treatment described was more complicated and consisted in an initial injection of emetine, pilocarpine, and ephedrine, which led to very violent vomiting. When nausea appeared "all types of liquor" were pressed upon the patient, together with draughts of warm water, which made vomiting easier. Apparently emetine is now used alone, though the details of treatment are not given in the later papers.<sup>4,5</sup> It is curious that emetine should be given by injection, since emetine causes vomiting by a direct local action on the stomach wall rather than by an action on the medullary centre; and it would be more logical to use apomorphine if a central emetic is necessary. Voegtlin, however, discarded apomorphine because its action was too short and because it made the patients sleepy. Possibly he used too small doses of emetine by mouth (from 0.5 to 1.0 gr.), for emetine by mouth should in theory be enough, without recourse to any injection. There has been a careful follow-up<sup>5</sup> of nearly all the patients, and out of the total of 1,042

<sup>2</sup> *Med. J. Austral.*, 1942, 1, 281.

<sup>3</sup> *Amer. J. med. Sci.*, 1940, 199, 802.

<sup>4</sup> *J. Amer. med. Ass.*, 1942, 120, 269.

<sup>5</sup> *Amer. J. med. Sci.*, 1942, 203, 525.

treated in 5½ years 86% abstained for six months and 76% for twelve months. About 60% abstained for three years; but after five years only 40% held off. The decline in the strength of the conditioned reflex is of course to be expected unless it is reinforced from time to time by a repetition of the treatment. Dr. H. Reese uses this method in Madison, Wis., on chronic alcoholics who appear in court and who wish to be cured; they are detained for thirty days. Reese regards it as the only effective method of treating alcoholics. They must, however, be willing.

### BLOOD GROUP FACTORS IN TISSUES AND BODY FLUIDS

For a long time it has been known that the specific antigenic substances of the ABO blood groups are not confined to the red blood cells. They are present in most tissues and body fluids—for example, in saliva, sweat, urine, digestive juices, milk, pericardial and pleural fluids, and in serum, but not in cerebrospinal fluid. They occur, too, in pathological conditions—in tumours and the fluids of hydroceles and ovarian cysts. It is thought that the A or B antigen in recipients' tissues and body fluids plays a large part in neutralizing anti-A or anti-B agglutinin in the plasma of universal-donor blood, while as a result of the interaction of antigen and antibody little or no anti-A or anti-B is found in pools of plasma or serum from donors of all the four blood groups. It has generally been considered that the blood-group antigens M and N occur only in the red cells, for several experienced workers have failed to detect them in tissues and body fluids, although their presence in malignant tumours has been reported, and Kosjakov and Tribulev in 1940 claimed to have found them in normal tissues. That the Rh antigen was similarly restricted to the red cells has been thought to account for the very damaging effects of maternal anti-Rh agglutinins on the red cells of her child in the production of haemolytic disease of the newborn, whereas antibodies of the ABO system reaching the foetus meet antigen not only in the red cells but also in tissues and body fluids.

A most important report of finding the M, N, and Rh antigens in tissues has been made recently by Boorman and Dodd<sup>1</sup>; they also found them in saliva, but in only small amount compared with the large quantities of A and B in saliva. They state that the Rh antigen is widely distributed in tissues, but is almost entirely absent from body fluids, perhaps because it is only slightly soluble in water. To explain the failure of the Rh antigen in foetal tissues to neutralize maternal anti-Rh and prevent haemolytic disease, Boorman and Dodd suggest that the absorption of agglutinins crossing the placenta from the maternal to the foetal circulation is effected by antigens in the body fluids and that tissue antigens play little, if any, part. Similarly, in the few cases in which the ABO system of groups may be the cause of haemolytic disease and the baby probably belongs to the "non-secretor" class, the maternal antibody is not neutralized because of the absence of antigen from the body fluids. Hartmann has shown that while the ABO antigens occur in the tissues of both secretors and non-secretors, and are present in alcohol- and water-soluble forms in secretors, they do not occur in water-soluble form in non-secretors and are therefore almost completely absent from their body fluids. Boorman and Dodd conclude that if the following two conditions are satisfied haemolytic disease of the newborn may result: (1) an incompatibility between the maternal serum and the foetal erythrocytes, and (2) an insufficiency of the corresponding antigen in the body fluids of the foetus.

If, as Boorman and Dodd's report of its presence in saliva suggests, the Rh antigen occurs in the body fluids, even in only small amounts, then its passage across the placenta from the foetal to the maternal circulations is easier to understand. How the Rh antigen, thought to be confined to the red cells, could get across the placenta has baffled everybody.

### OCCUPATIONAL THERAPY IN NEW ZEALAND

So successful is the front-line convalescent depot run by the New Zealanders in the South Pacific that 95% of battle, accident, and sickness casualties return to their units as Grade I fighting soldiers. This depot fills the dual role of reducing front-line wastage to a minimum and of tackling the problem of rehabilitation at its source. The depot promptly repairs, salvages, and rebuilds. Many of the staff worked at the remedial hospital at Rotorua, which treated military cases from all over New Zealand, and they have a wealth of practical knowledge. Each patient progresses through stages of exercise which are interesting in themselves and which help him to forget his ailment. No one has a chance to brood; he can walk, play, read, and learn something about gardening, bookkeeping, art metal work, or whatever interests him. Those who have undergone amputation get from occupational therapy an immediate training in some art or craft—a new interest and stimulus in life. This front-line depot is a highly successful experiment as a prelude to the wider facilities available at the newly built modern establishments in New Zealand for the treatment of all disabled soldiers.

### IRRESPONSIBLE JOURNALISM

In recent weeks medical organizations and practitioners have had a flood of inquiries, mainly from the North of England, as to the value of vitamin D in the treatment of arthritis. Most, if not all, of these inquiries can be attributed to an unsigned article published in a popular newspaper at the end of last year, in which high hopes of a cure by this treatment are held out to sufferers from arthritis. How much this article owes to an article printed in an American periodical a few weeks earlier is perhaps a matter for speculation, but there is no doubt as to informed American opinion on this kind of medical journalism in general, and on the treatment of arthritis with massive doses of vitamin D in particular. In a leading article in the *Journal of the American Medical Association*<sup>1</sup> irresponsible journalistic efforts of this nature are rightly and roundly condemned, and the treatment in question is put in its proper perspective with the following quotation from *New and Non-official Remedies, 1943* (Council on Pharmacy and Chemistry of the American Medical Association): "Clinical evidence does not warrant the claim that massive doses of vitamin D are of benefit in chronic arthritis. . . ." This view is doubtless shared by the majority of medical men in this country who have had wide experience in treating arthritis and of the diverse methods that have been advocated from time to time. The distasteful task of shattering the falsely raised hopes of chronic arthritics is one that might well be spared the already overburdened practitioner and official. It is, however, the disillusioned sufferer who is most in need of sympathy, but it is hard to see how these distressing incidents are to be avoided unless lay journalists writing on medical topics can be persuaded to be factual instead of sensational.

# NEW CHOLECYSTOGRAPHIC MEDIUM. . . .

● Glaxo Laboratories Ltd. present PHENIODOL in granule form.

Pheniodol is the name given by the General Medical Council to the new oral cholecystographic medium which has already received favourable mention in Continental medical literature, and has produced successful results during official clinical trials held in this country. The chemical formula is  $\alpha$ -phenyl- $\epsilon$ -(4-hydroxy-3:5-diiodophenyl) propionic acid. Pheniodol Granules are not likely to produce unpleasant side effects, such as burning of the throat, nausea, and diarrhoea, firstly because the drug does not come in contact with the mucous mem-

brane of the mouth and throat, and secondly because efficient dispersion aids absorption.

Pheniodol Granules therefore present the radiologist with an improved oral means of obtaining a trustworthy picture of the normal gall bladder, even under conditions which interfere with optimum intestinal absorption. The shadows obtained compare favourably with those produced by other cholecystographic media. Subsequent operations have shown that absence of shadow has been due to a diseased gall bladder. Dispensing is simplified as the granules require no preparation, being swallowed with the aid of drinks of water.

PRODUCT OF THE  
GLAXO LABORATORIES

## PHENIODOL

**GRANULES:** Glass tubes each containing 3 g. of Pheniodol in about 6 g. of granules in packs of 1 and 8 tubes.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX. BYRON 3434

# 'NEO-HALARSINE'

TRADE MARK

BRAND

## arsphenoxide tartrate

has been produced specially to meet the growing demand for an arsenical suited to the shorter and more intensive methods of treating syphilis. Repeated tests indicate that, both in the destruction of superficial treponemata and in the reversal of positive serological reactions, 'Neo-Halarsine' compares favourably with neoarsphenamine.

The average dose for an adult man is 0.09 gramme, for a woman 0.06 gramme.

Solutions retain their full therapeutic efficacy and freedom from toxicity for at least twelve hours after being made up.

Supplied in ampoules of 0.045, 0.06 and 0.09 gramme packed singly or in boxes of ten.

Manufactured by  
**MAY & BAKER LIMITED**

Distributors

**PHARMACEUTICAL SPECIALITIES (MAY & BAKER) LIMITED, DAGENHAM**

# FOR GENERAL PRACTICE

Trade **'PROSCABIN'** Mark

Brand of BENZYL BENZOATE EMULSION 25%

For the treatment of scabies.

Bottles of 4oz., 20oz., 40oz.

Trade **'CIGNOLIN'** Mark

(The Original Product)

Brand of DITHRANOL B.P.

Indicated in psoriasis, alopecia areata,  
"athlete's foot," etc.

Powder in tubes of 1 g., and boxes of 10 g.

Trade **'SALYRGAN'** Mark

(The Original Product)

Brand of MERSALYL, B.P.

A powerful diuretic, indicated in cardiac  
and renal œdema, ascites, Ménière's  
disease, etc.

Ampoules of 1 c.c. and 2 c.c., in boxes of  
5 and 25.

## DIETARY SURVEYS

## CONFERENCE OF THE NUTRITION SOCIETY

A whole-day conference was held last month at the London School of Hygiene and Tropical Medicine, to discuss budgetary and dietary surveys of families and individuals. The subject was introduced by Sir JOHN BOYD ORR, F.R.S. Since nutrition will be the most important factor during post-war reconstruction, the duty of the research worker must lie in supplying the facts upon which the legislator may base his action.

## How Much is Spent?

Mr. A. G. JONES of the Ministry of Food discussed the possibilities of finding out the adequacy of nutrition in the community by means of budgetary analysis. This method was based, he said, on the study of purchases and expenditure, and gave a comparatively rough indication of the dietary intake. The budgetary survey, moreover, yielded data relating to the family as a whole, rather than to the individual members of the house, who might receive more or less than their fair share of the food available. The housewife had first to provide a statement of the stocks of food in hand. She must then account over a stated period, usually one week, for all the food used, whether taken from stock, purchased, received as gifts, or grown on the allotment. Meals taken outside the house must be allowed for by reducing the estimate of the number of persons fed, at the rate of 5% of one person's total week for a midday meal, or 2% for other meals. A man having six midday meals out would thus count as only 70% of a man in the final division of the total weekly food intake by the number of persons in the family. Corrections in the opposite direction must be applied for meals given to visitors, or for food wasted or given to animals. Small items such as sweets, snacks, chipped potatoes, and drinks might be ignored. At the end of the week the stock of food in hand was again counted.

Certain difficulties in taking a fair random sample of the population for survey could not be overlooked. The compilation of the budget was laborious, and mothers with small children might decline to participate. Outside observation might also introduce unusual psychological factors. The housewife might feel on her mettle to provide good meals for her family and to avoid wasting food. In subdividing samples of the population according to income a complication arose on account of the different expenses which the "house-keeping money" was intended to cover in different families. There was urgent need for standardization in interpreting the results of surveys. In particular it was difficult to convert data relating to children into "man units," because the needs for the various nutrients were not related to the adult need in the same proportion. Thus the protein need of the growing child would be relatively greater than the carbohydrate need.

## How Much is Eaten?

Dr. E. R. BRANSBY, also of the Ministry of Food, said that dietary surveys might be related to units of different sizes. Thus a statistical study might be made of the food resources of a whole country. By this means Orr had recently estimated that to supply everybody in this country with proper nourishment meat production would have to be increased by 25% and milk production by 65%. Other surveys had been based on a more detailed examination of the food consumption of smaller groups, such as institutions and families, and of individuals. An important object of family surveys was to find the effect on food consumption of such factors as income and family size. Social class also seemed to influence the choice of food—e.g., in the greater consumption of milk by "professional" families than by working-class families enjoying the same incomes. Three types of study were generally employed. The "precise" method (developed in America by Atwater and first used in this country by Noel Paton in 1900) involved the weighing of items of food before they were eaten. It was so slow and laborious that it was difficult to obtain the co-operation of a properly selected random sample of the

population. The "logbook" method was much simpler, and had been used successfully for four years in the Wartime Food Survey. A record was kept of all food as bought, or a careful estimate was made of the amounts of food used as they were eaten. In the "questionnaire" method the informant was asked to record at one interview all her purchases over a previous period. In this method inaccuracies were almost certain to occur. A golden rule for all comprehensive dietary surveys was that food data should be recorded immediately either after purchase or before consumption. Data supplied from memory must be regarded with suspicion. There was, however, much scope for the development of short-cut techniques in dietary surveys. Estimates of the food as eaten might be made in homely measures, the housewives being provided with standard tablespoons and teaspoons, together with diagrams of pieces of food of different sizes. Plaster models of helpings of meat, vegetables, etc., would be even more useful if obtainable. In the statistical analysis of data an immense amount of time and labour might be saved by using punched cards, which were fed into an appropriate calculating machine.

The degree of accuracy of the results of dietary surveys was open to discussion. In 1937 McCance and Widdowson stated that by the use of tables of food composition individual food intakes of the various nutrients could be very accurately assessed. While this might be true for the average nutrient content of a number of diets, there was not enough experimental evidence for such a definite conclusion in regard to individual diets, in the estimation of which numerous sources of error must be recognized. A grading of the intake of each nutrient as good, fair, poor, or very poor was probably as much as might be expected. Statistics as to the influence of the number of families examined on the reliability of the data obtained were important in order to minimize the labour of conducting surveys. A recent calculation had shown that collection of data from 100 families yielded as much information as from 300 families.

## Housewives' Data

Mr. F. LE GROS CLARK of the Children's Nutrition Council next went into the question of the allocation of food within the family. He pointed out that when the supply of food was just enough for the adequate nutrition of the family when distributed in the best possible way, any faulty distribution must result in the malnutrition of the less-favoured members. Investigation of the distribution was made difficult by social prejudices. If housewives were asked for intimate details of their economy they usually became suspicious, and so far only minor attempts to solve the problem had been made. In any working-class family one suspected that the mother would be the worst-fed member.

Miss MARGARET GRANT of King's College of Household and Social Science reiterated the difficulties involved in dietary surveys, and in the comparison of the results of different workers. Her experience with students had shown that the proper recording of all dietary items was very laborious. A second portion of any dish might be refused in order to avoid the trouble of re-weighing, or the very conscientious student might accept unwanted second portions merely to counteract this tendency. The worker should have no official connexion with the people examined, since their conduct must not be influenced by desire to please, either to obtain favours or to avoid disciplinary action. Realization of the difficulties of obtaining accurate records from students, who had plenty of time to spare for the work, made Miss Grant sceptical of the value of data supplied by housewives, who were usually overworked without any additional responsibilities.

Miss D. E. HOLLINGSWORTH of the Ministry of Food mentioned the work of the Wartime Food Survey. During 1943 about 1,000 families had been visited each month, representing 3,000 individuals. Refusals to collaborate had mostly been from middle-class families. The problems investigated had included the effect of prices on the purchase of foodstuffs, the costs of nutrients when bought as different foodstuffs, the amount of vegetables available for purchase, particularly in Scotland, and the amounts of nutrients derived from rationed and unrationed foodstuffs respectively. In many instances spontaneous comments had been written by housewives on

the backs of their ration books, and these were given full consideration.

The value of the "questionary" method was defended by Miss M. W. COOPER of the Oxford Nutrition Survey. An intelligent visitor could obtain a wealth of information in the course of an hour's interview, with a careful inspection of the housekeeping budget and accounts. The agreement between the estimated expenditure and expenditure actually accounted for was much closer in lower- than in higher-income groups, presumably because a poor woman had to take greater care in spending her money. Dr. B. WOLF suggested that the value of nutritional surveys would be much increased if the previous health histories of the families concerned were collected.

### Large-scale Surveys

The organization of large-scale surveys was described by Mr. L. MOSS of the Wartime Social Survey, a social research unit working for Government Departments. He thought that, since nutrition was becoming accepted as an agreed national interest, research workers should not allow present shortcomings in accuracy to stop them from organizing large-scale surveys. The methods used must take due account of social factors, which might be as serious in their effect as biochemical factors. Over the last two years Dr. Gertrude Wagner and other workers of the Wartime Social Survey had participated in nutrition surveys which fell into three main types: (1) studies of the kinds of food eaten in different groups of the population, together with such questions as when and where meals were eaten; (2) studies of the consumption of particular food items such as oatmeal, potatoes, or milk; (3) studies of cooking habits or the methods used in preparing and cooking certain foods. The arrangements for large-scale surveys must be very carefully made. Since the nutrition expert could not exercise personal control over the collection of all information, he must give precise and detailed instructions for the collection of information. But before formulating his instructions he must have an adequate knowledge of the people who were to be the subject of the investigation, and it was here that the sociologist played his part. To obtain a fair degree of precision and detail in the material resulting from surveys the persons who actually collect the data must be well trained in social research. Some scientific training was also desirable, in order that they might understand exactly what kind of information was required by the nutrition expert. The recent survey on cooking habits was a good example of the need for collaboration between laboratory worker and sociologist, the former discovering the conditions essential for the preservation of nutrients, and the latter finding how far these applied in common practice.

If the results of surveys were to be put to national advantage the nutrition research worker must ensure that his material was representative of large groups. A useful device, employed by the Survey to find out for the Ministry of Food what items entered into the diets of civilians, was to stratify the subjects into groups according to employment, and to take random samples within these groups. Thus the population was divided into light and heavy factory workers, outdoor workers, clerical workers, and housewives. The amount of detailed work was large, and the mass of data might become overwhelming if handled by ordinary methods, but this difficulty might be overcome by mechanical tabulation.

### Questions of Accuracy

Prof. M. GREENWOOD, F.R.S., spoke on the statistical validity of methods used in budgetary and dietetic surveys. It was satisfactory that the most recent value of about 3,200 calories calculated from budgetary surveys for the energy requirement of an average man doing an average day's work was in excellent agreement with the figure worked out 30 years ago by means of direct calorimetry. By both methods the variation between individuals of the same weight and activity was about 12%. Budgetary surveys had indicated wide variations in the amounts and quality of food bought by different families, but the physiological and pathological effects of these differences could not be appraised without long and continuous observation. Mere determinations of the calorific intake of a community in a stable state of nutrition would do nothing more

than verify data which had already been verified *ad nauseam*, but the information obtained might be valuable in an unstable state of nutrition by allowing the rapid detection of disequilibrium. An experiment carried out at Millbank Penitentiary in 1822, and the experience of the Army at Kut-el-Amara in 1916, suggested that the critical level for a population compelled to do moderate manual work was not much below 2,600 cal. In 1924, and again later, the budgetary survey method was used to assess the calorific intakes of miners during economic distress. In each instance communities were found whose intake was dangerously near the critical level. The children of Durham miners' families, with an intake of only 2,830 cal. per man unit, were found by anthropometric examination to be below the average for the county.

Wing Cmdr. YATES suggested that in dietary surveys a wide field might first be covered with a low degree of accuracy, and after this preliminary orientation a small field could be studied with a higher degree of accuracy. Dr. JOHN YUDKIN mentioned a survey in which mothers and children in families which spent less than 7s. 3d. per person per week on food were found to be inferior in various ways to those in families spending more. Prof. J. R. MARRACK criticized the view that in large surveys errors would inevitably cancel out. This would not be true of systematic errors, such as that introduced by the refusal of certain types of housewife to collaborate.

### Family Spendings

"The Family Income and Variation of Expenditure on Food" was the subject of a paper by Prof. A. L. BOWLEY of the Oxford Institute of Statistics. He translated into mathematical terms the generalization which stated that, with increase in income the expenditure on primary needs increased absolutely, but diminished as a proportion of the income. Thus examination of a recent collection of budgets indicated that when the income per "man" was 209 to 239 pence per week the expenditure on food was 53%; when the income was 420 to 475 pence the expenditure on food was only 42%. In making these calculations allowance must be made for savings, and for the inclusion in the family of lodgers and of children old enough to contribute part of their earnings to the family income.

Dr. R. F. GEORGE suggested that "income recipient" was a better term than "earner," since persons receiving pensions, etc., were included. The period of one week was too short for surveys of expenditure, since there might be great variation from week to week. Items such as clothing and furniture occurred at irregular intervals. Meals taken at school and canteens complicated calculations of expenditure on food. The present disintegration of families introduced another difficulty. Domestic conditions after the war might possibly be so changed as to make all previous surveys have little more than historic interest.

Dr. CARADOG JONES of Liverpool University went into the relation between expenditure on food and on other items. "Cost of living" was related to expenditure rather than to income, and with families having the same income expenses might be high in this running into debt and low in those saving. A general tendency might be noticed to consider things that were customary as being necessities. On this standard an adequate diet was one which would support existence without too much absence from work. The percentage of the income spent on food, rent, and fuel decreased as the income rose. Thus in very poor homes, which incidentally contained the most children, 50.4, 25.8, and 11.8% of the total income was spent on these three items in the order given; in middle-class homes the proportion was 20.1, 10.8, and 5%. In compensation, expenditure on "miscellaneous" items was much greater in the rich than in poor homes, being 55.8% as compared with 7.5%. The cost of living was much greater in urban than in rural areas, but attempts to adjust pensions, etc., between town and country dwellers on this basis had often led to confusion.

Mr. C. MADGE emphasized the divergencies in expenditure on food that might occur in families with the same income. In a survey in Leeds in 1942 two sets of families of the same numbers and incomes were made up for comparison whose mean savings amounted to 4 and 14% of their incomes

respectively. In the first group 45% of the total income was spent on food, and in the second only 41%. The families with lesser savings also spent more on tobacco, and it was noteworthy that in other families with more than two children more money was usually spent by the father on beer and tobacco than was devoted to the upkeep of the additional children. It seemed desirable to educate certain sections of the community to buy more food. This particularly applied to elderly persons, who in the past had been expected both to work little and to eat little. With the rising average age in this country it might be necessary to encourage more vigour, and better feeding, in old age. Examinations at Peckham Health Centre had indicated another type of person, young in years but suffering from anaemia, and restrained and unenterprising in behaviour, who might benefit if persuaded to spend more money on food.

Mrs. FOWKE described a survey carried out on a group of adolescent boys whose individual appetites and preferences were spread over such a wide range that the caloric intakes varied from 2,000 to 4,185 cal., and the vitamin A intakes from less than 2,000 to about 9,000 i.u. daily. Dr. B. WOOLF criticized the adequacy of the B.M.A. standards for nutrition. He calculated that on the basis of these standards it would not be necessary, as urged by Orr, to increase the production of milk and of other protective foodstuffs, but that considerable reductions in all foods except wheat could be allowed. The monetary allowance for food, according to Beveridge, fell slightly short of the amount necessary for adequate nutrition, but the provision for clothing was so low as completely to upset the balance of the budget. Much of the money earmarked for food would inevitably be used for clothing.

#### "Nutrition Works"

Sir JOHN ORR, in concluding the proceedings, commented on the difficulties inherent in dietary surveys, and stressed the need for uniformity in the presentation and interpretation of results. His own experiments on giving extra milk and oranges to children had justified him in the belief that "when you apply nutrition, it works." The Government was committed to a scheme to improve the diet of this country to a level consistent with optimal health, though its plans might take years to complete. Sir John would hesitate to criticize those who in order to enliven drab lives diverted a few shillings which might be spent on food to buy beer or visit a cinema. We were living in a world of potential abundance. When the powers of war production were redirected to meet the requirements of a peaceful world, wages and the price of food should be adjusted so that all should enjoy not only the necessities of life but also some of the amenities.

#### VOLUNTARY HOSPITALS AND THE WHITE PAPER

Representatives of the 1,100 voluntary hospitals in Britain, at a conference in London on March 7 arranged by the British Hospitals Association, asked the Government to reconsider certain proposals in the White Paper on a National Health Service.

A resolution, proposed by Lord Southwood and carried unanimously, expressed sympathy with the Government's intention to secure a co-ordinated hospital and consultant service accessible to every member of the community regardless of income, but viewed with grave concern the administrative and finance proposals in the White Paper, and added: "The suggested administration does not constitute that partnership between local authorities and voluntary hospitals which has been the avowed intention of successive Ministers of Health, and which is an essential requisite to the effective participation of the voluntary hospitals, and therefore to the accomplishment and efficiency of the scheme, and does not—except partially in the case of Scotland—furnish a suitable organization. The financial proposals are inconsistent and unacceptable in that they afford part payment only to the voluntary hospitals for their services rendered under the scheme, while postulating that the financial gap thus caused must be filled by benefactions and other voluntary gifts. At the same time, by the offer of free service for all, they destroy the incentive of the public as a whole either to give or to contribute."

Sir Bernard Docker, chairman of the B.H.A., presided over the conference, and it was decided to send copies of the resolution to the Minister of Health and the Secretary of State for Scotland.

## Correspondence

### The Prisoner-of-War Mentality

SIR.—Major P. H. Newman's masterly article (Jan. 1, p. 8) is one which merits the widest possible publicity, and should be ingested, digested, and absorbed by every authority, organization, or person—official or non-official—likely to be concerned in moulding the future of returning prisoners-of-war. To further the gastro-intestinal analogy, Major Newman's presentation of his own observations on his comrades during a long and trying imprisonment is so "personal" and valuable that absorption should allow no subsequent excretion—there is no waste.

As one who has, shall we say, sampled this "valley of darkness"—and I believe it is but a sample compared with Major Newman's stretch—may I be permitted to make one or two observations of my own. Adopting his four stages: (I) In the breaking-in period the captive's physical lot is hardest, while his mental and moral anguish has been adequately described. From my own observations there quickly develops, during a varying period of semi-starvation, the outstanding mental reaction of prisoner-of-war life—namely, "food consciousness." He acquires a marked "food complex," a manifestation of self-preservation which will persist throughout the P.O.W. days and probably for some time after his ultimate release. Food, usually favourite dishes, is the main topic of conversation and of thought; and, yea, even invades one's fitful slumber. To be personal for a moment, I well remember dreaming on two consecutive nights of omelettes and treacle pudding—alas, but a dream, and rude was the awakening. Either was as obtainable as a slice of the moon.

Again, during Major Newman's second stage—the convalescent period—some fail to pull themselves together for a long time. Given equal conditions there begins a true test of the individual's fibre. In some the superficial veneer of "culture" is readily stripped, and a small proportion, even of the so-called officer class, degenerate, become spiteful, petty, dirty, even dishonest—"primitive." In this minority social behaviour disintegrates and "each man for himself" becomes the code. Happily, by far the majority stand up to it well, officer and man.

During III—the long period of boredom—my impression has been that sexual deprivation, as defined by Major Newman, is dwarfed or overshadowed in importance by the "food-fear complex," or, at least, that the latter is an equal runner-up. The one would appear to depend largely upon the other in that when the "food stakes" are comparatively good, then the "food consciousness" abates. The keen, almost pathetic, anticipation with which the prisoner awaits the life-saving Red Cross food parcel vies with his eagerness to receive mail from home. These two facts, indeed, share the honours as the high lights of his existence. To add to Major Newman's observations, it is astonishing, in my experience, how apparently absent is normal sexual desire and inclination. If the subject ever crops up at all, one has frequently heard it expressed, "I seem to have no urge at all." At least, one heard little or no sex talk, unusual in a one-sex community, living on top of each other. I knew of only one case of homosexuality in the camp, while masturbation seemed to be rare. Before capture the majority of prisoners have already experienced a varying period of action in which their physical and environmental conditions may be comparable with those of prison camp. Already, to some extent, the prisoner is hardened to sexual deprivation. He becomes "anaesthetized" in due course to separation and all it entails. A somewhat crude illustration is afforded by a question which on one occasion went from man to man round the camp. One was asked to make an immediate choice between three things: "a seven-course dinner," "a woman," or "a bottle of whisky." The subsequent analysis was heavily in favour of the last named—obvious "escapism." They were equally obtainable!

Finally, regarding Major Newman's fourth stage—the repatriation period—it is obvious from his excellent observations that the P.O.W. of long standing merits a long period of

psychological readjustment on his return home, and should be very compassionately handled. As Dr. Billings points out (Jan. 15, p. 90), our men and women in Japanese hands will ultimately return, a large proportion of them mentally and physically shattered as a result of experience far worse than those of the average prisoner-of-war in German or Italian hands. I agree with Dr. Billings that the magnificent and life-saving Red Cross organization, to whom the prisoner is anything but "written off," should be entrusted with this problem: they and they alone. I believe that any Government organization devised for this purpose, or any body savouring of authority or officialdom, would be psychologically wrong, and would immediately antagonize the returning prisoner-of-war in need of help.

Excellent as are Major Newman's outlined principles regarding the establishment of this organization, I feel that the formation of P.O.W. clubs, as such, is inadvisable. More than once has one heard expressed, "I never want to see anyone in this camp again," or, "Even my best friend [in the camp] gets on my nerves," etc. Not only does the P.O.W. want to bridge the gap in his life and make up for all he has lost, but he wants to forget. He will probably warmly welcome his best friend in his own home, but not, I feel, in any communal atmosphere. As Major Newman observes, advice, help, and treatment must be unobtrusive, sympathetic, skilled, and, above all, personal and individual; I suggest, preferably within the confines of, or centred from, his own home, where are concentrated all his longings, thoughts, and desires.—I am, etc.,

Sonning Common, Reading.

A. W. VAUGHAN ELEY.

### Nursery Schools and Classes for Young Children

SIR,—Referring to the letter of Dr. Janet Aitken (March 4, p. 335), I would support whole-heartedly the opinions expressed in paragraphs 2 (b) and (c)—that the responsible staff of nursery schools or classes should have had special training and experience in the handling of these children both from the mental and physical aspects, should have had a grounding in practical hygiene, and that there should be the closest co-operation with the various health services. At the same time it is an arguable point whether children can best be accommodated in nursery schools or classes. It should be possible to attain these ends in a nursery class just as well as in a nursery school. Nursery schools or classes should be within easy reach of the child's home, and if the principle of nursery schools is rigidly adhered to it may involve the establishment of small schools difficult to supervise from the health point of view. Furthermore, if the young child is placed in a nursery school, it will involve a change of school at the age of 3 years and an interruption of continuity, which is most undesirable.

Experience of nursery classes attached to infants' schools has shown that the right emphasis can be secured in such cases, and that it is by no means the case that the main interest is on education rather than on health.—I am, etc.,

A. A. E. NEWTH,

Senior Medical Officer,  
City of Nottingham Education Committee.

### Babies in Glass Cages

SIR,—I wonder if Prof. Parsons would be interested to know that I saw a series of small glass cubicles in the von Pirquet Hospital in Vienna ten years ago. I was told that these had been tried extensively and found to be useless because the babies became lonely, frightened, and lost weight when nursed in them. I never saw the cubicles in use because they had been abandoned when I was at the hospital. It appears that this idea is antiquated and possibly harmful if the opinion of the originators is to be trusted.—I am, etc.,

London, W.1.

CLIFFORD ALLEN.

### Fainting in Blood Donors

SIR,—Publication in your columns was recently made (Feb. 26) of a report to the Medical Research Council prepared by a subcommittee of the Blood Transfusion Research Committee. The report was intended "(1) to identify factors that may be associated with fainting during blood donation, with a view to their correction; (2) to determine the frequency of delayed faints." A total of 362 cases of fainting with a control group

of 335 were investigated in admirable detail at several centres in regard to sex, age, civil state, relation to food, menstruation, time of waiting, difficulties in bleeding, numbers of previous bleedings and faints, etc., and in 4,212 cases information was obtained as to the incidence of "delayed faints."

The observations made cover three and three-quarter pages of the *Journal*, are presented with clarity and precision, and are, as a statistical preparation, beyond reproach. The investigators found, or at any rate record, no significant difference between those who fainted and the controls, the only material point emerging from the careful series of conclusions drawn being that it would be better not to use people who faint as blood donors. *Parturient montes!*

We are all acquainted with the type of person who faints at vaccination or in church or at the sight of blood, and have little difficulty in arriving at a clinical assessment of their condition. The findings of the subcommittee would have been different had they offered any observations on the emotional stability of the contrasted groups; it might at any rate have given the report some practical value.—I am, etc.,

London, W.1.

JOSEPH GÉOGHEGAN.

### India's Population Problem

SIR,—Drs. Barrow, McCracken, and Culbert, in their letters, dwell upon that pessimistic gloomy outlook for the future of India which I evidently possess. Nothing could be further from the truth than this assumption, and I hereby relinquish all claim to the Deanly attribute of Gloom. Nor can one who has voluntarily spent a large part of his life in medical research in the Tropics of Africa be accused of pessimism. On the contrary, he reveals himself an optimist, not worldly wise perhaps, even a little misguided—going far afield to pursue the shadow, instead of remaining at home to collect the substance—but assuredly an optimist, and a pretty nearly incurable one at that.

Dr. Prem comments with a slight touch of asperity on the position of civilian doctors in India; according to his account it is not the larger numbers of Indian doctors, but the smaller numbers of British doctors there, who control all the highly paid key posts and frame the policy; they derive their instructions from Whitehall and "have the real power." What is this mysterious "power" of which he writes? Is anyone preventing him or his Indian colleagues from carrying out, among their own people, the duties for which they have been educated and for which they are qualified—namely, the treatment of the sick and the prevention of disease? Dr. Prem observes that my reference to the Atlantic Charter will make Indian readers of the *Journal*, and many others, very suspicious—a remark so cryptic that I feel quite unable to cope with it.

Industrialization of India is advocated by Dr. Prem as the solution. Dr. Barrow points out that India is producing only enough food to give 88% of its existing population a daily ration of 2,800 calories per head, even if none were exported and there were no maldistribution. Dr. Forrester notes that India has plenty of raw materials and that industrialization will come. He quotes the Hot Springs Conference report, Section II: "The real clue to the solution of the problems of agricultural over-population lies in industrialization . . . [it] is also necessary if we are to raise the general standard of living." This admits that agricultural overcrowding exists, and, by implication, that the standard of living is low. Dr. Marrack makes a useful contribution with reference to the bearings of the Hot Springs Conference report. Several writers mention increases of population in Western countries exceeding those recorded for India.

The case as stated by me is plain enough. It is that the population in India has long suffered, and suffers now, from great and fatal epidemics and from high maternal and child mortalities, which are largely preventable by modern methods. I have assumed that it will be the future aim of all Indian doctors to prevent these diseases. In that case, given the staff, materials, and financial means, they will succeed. As a result, the figures of increase of population in Western communities—none of which suffers from more than a mere fraction of the preventable diseases of India—will quickly be exceeded by the Indian figures; the problem of the maintenance of the population will then become acute in that country.

Dr. Barrow states that the birth rate in India is apparently declining, being 34.5 in 1934-8 as against 35 in 1921-30 and 38 in 1901-10. Dr. McCracken tends to agree with Doubleday that over-feeding checks increase of births. Dr. Forrester, who advocates industrialization, points out that urban populations are less fertile, and that industrialization will reduce the birth rate. If all this is true, good and well. But the employment of this line of argument by

those who profess to regard restriction of population as an undesirable thing does seem a little surprising. Dr. Forrester, in pointing out a series of matters which he states I have overlooked, gives as his No. 4: "Man is both consumer and producer. To-day in India 50% of all deaths are of children under 10. From another standpoint this means that a great proportion of the population never functions as fully efficient producers. Every lengthening of the span of life, if it is coupled with adequate nutritional intake, increases the producer period of a man's life." If Dr. Forrester had only added "and also increases the consumer and reproducer period of a man's life," he would have stated quite clearly what is a very substantial part of my case. It is exactly these increases, following automatically and swiftly upon the application of modern preventive methods, that I anticipate will give rise to the consequences of over-population.

Dr. Forrester refers to my "... uncompromising acceptance of the validity of the Malthusian doctrine." No one who has read my article will accept that description as a correct representation of what I wrote about the views of Malthus. The term "Malthusian" is rather overworked by many of those who have taken part in this correspondence, and a word may be said about it. There are few countries of which it can be affirmed that they hold exactly enough people. The majority are too full or too empty. Countries with a standard of living that is accepted as reasonable must augment the means of subsistence as rapidly as the population grows or else prevent increase of their numbers. If they do neither of these things, their standard of living must fall. Malthus recognized this simple truth, but by publishing it he evoked a controversy which has not yet died. Like "Capitalist" and "Communist" to-day, "Malthusian" became a handy term of abuse. There was even greater dialectical magic in "Malthusian" than in either of these two modern words. All who felt so disposed slung "Malthusian" at any who had the effrontery to believe it possible that the overcrowding of any place could ever occur. Debate by epithet had, of course, as much convenience in those days as it has now. It was acceptable to many, since it dispensed entirely with any need for the use of rational processes. As a substitute for the effort of thinking "Malthusian" acquired really amazing virtues.

But Malthus was not the first person to grasp one important fact—namely, that an acre of land is a measurable, finite thing, devoid of the well-known properties of an expanding suitcase. Unless a miracle happens, the acre of land which just supports a man and his wife will fail to support them at the same level of comfort when they are plus five children. Centuries before Malthus, Plato made shrewd comments upon this topic: yet even he did not claim any priority for his views on account of their then great novelty. Probably in those days his ideas were already well established in the traditional lore and were fully at the service of any person of average intelligence. In Plato's Laws the land allotted to each citizen of the proposed ideal State was to be preserved intact, not to be added to or subtracted from, not to be given away or sold. So long as it was properly used it should remain the possession of the owner and his descendants. But in order to make this possible the family of the successive owners was to be definitely limited, so that each generation should equal, or, at least, not exceed, in numbers the previous one; otherwise the whole system would break down, because the land would not support the extra population. Provision was therefore to be made in the State for the necessary official regulation of the size of families.

Referring to Malthus and Henry George, Dr. Forrester says, "But neither of these is to-day usually regarded as the greatest of economists or even of experts on population problems." The views of these two writers were briefly discussed in my article. As regards George, his principal remedy for economic ills was the taxation of land values. I do not know whether he is regarded as "the greatest of economists" or not. But it is hardly out of place to mention Martin Leake's statement that even now every acre of India has its value assessed each thirty years, so that a beginning at least has been made in this direction. The system of taxation of land values is in full force in many parts of Denmark, Australia, and New Zealand. These countries cannot be classed as backward with regard to health matters; in point of fact they all rank among the most advanced. Therefore, one cannot help believing that if an economic principle, whether recommended by George or anyone else, is considered good enough for such progressive countries as these, there is likely to be something of value in it from the health point of view.

When the devastating Indian epidemics of cholera, plague, kala-azar, malaria, and other diseases are eliminated, when the maternal and child mortalities are reduced to low rates, an enormous Indian population, which is now lost, will survive; Sir John Megaw and other authorities have long recognized this. Encouragement of early marriage with the production of large healthy families, if this can be achieved without detriment to the health of the mother, is a policy which can justly be advocated for a country with abundance of good land still available, but it may be, and indeed is likely to be, a dangerous one for already crowded countries. Restriction of some kind will become necessary; it may be brought about as a

result of education or social convection, or by other means. The methods which Dr. Stopes has so courageously sponsored for the relief of the individual poor mother in the overcrowded home may yet prove to have their most valuable application to the overcrowded State.

During the post-war period, in a medically progressive India, there is likely to be a race between a growing population and adequate provision for its maintenance. Experience shows that agrarian and industrial reforms are as a rule slowly effected, whereas medical reforms may be relatively rapidly made, especially in tropical lands. If medical reform takes place in India the other reforms will have to be on an unprecedented scale and also executed at great speed. Any administrators who achieve a reasonably good standard of living for the future population of India will deserve well of their country, and there is no one who will not wish them all success in the task.—I am, etc.,

School of Tropical Medicine, Liverpool.

### Publication of Anaesthetic Misadventures

SIR.—In Dr. J. Elam's letter (Feb. 19, p. 263) he puts forward a strong plea for publication of anaesthetic misadventures. Towards the end of his letter he hopes that by such publication "the general public, too, might then begin to understand their foolishness in not paying more attention to . . . anaesthesia." I think the folly of the public lies in not paying more for anaesthetic service.

He bemoans the fact that a surgeon of a county hospital states that "the anaesthetics are given by house-surgeons, many of whom have no previous experience." The general public would be much more distressed were they to realize this. Surely the house-surgeon can gain his experience under the guidance of the anaesthetist on the hospital staff. The blame lies with the surgeon who allows the inexperienced house-surgeon to administer the anaesthetic, unless he is prepared to accept full responsibility from beginning to end.

I would offer the following suggestions: (1) Educate the surgeons as to modern anaesthetic procedures and requirements. (2) Assure the general public that increasing safety and comfort in anaesthetic technique is available and that they should be prepared to pay for it. (3) Invite, say, the department of anaesthetics at Oxford to investigate all cases of anaesthetic misadventure reported to them, and that they publish their comment upon them. (4) Invite all anaesthetists to subscribe annually towards the cost of such investigations and reports.—I am, etc.,

Salisbury.

A. D. H. SIMPSON.

### Reform in Medical Education

SIR.—I agree with much of Mr. G. H. Colt's letter (Feb. 26, p. 307), but I think that his summary dismissal of the preliminary sciences is a serious mistake. Even so elementary a theorem as the parallelogram of forces is constantly disregarded by the orthopaedic surgeon (cf. Charnley, *Lancet*, Feb. 19, 1944), and Mr. Souttar made equally elementary physics the basis of his Bradshaw lecture (*Journal*, Dec. 11, 1943). Prof. Christie's Goulstonian lectures (*Journal*, Jan. 22 and 29, 1944) showed the influence of simple mechanics on emphysema, and the plain fact is that we have hardly begun to realize the importance of these fundamental sciences in our preoccupation with more flashy ideas. Doctors send patients for x-ray examination, etc., for gall-bladder disease or appendicitis (probably 95% of which could have been satisfactorily diagnosed by simple clinical examination), and think that they are practising scientific medicine. It is as if one became a scientist by using a spectroscope to see whether the grass was green or the sky blue. Not that I undervalue these wonderful new diagnostic aids—for even the spectroscopic examination of the sky has its uses—but for one who has been trained to use his mind and senses aright they are largely unnecessary. They are for the specialist, and the more the medical student is taught to do without them the better doctor he is likely to become. He should know of their existence, as he should also know about the existence of the various types of bacteria, but he need not know how to recognize them; and, as Mr. Colt suggests, most of his bacteriology can be cut out without serious loss. The same is true of his pathology (I

regret to say it), though he cannot know too much of the pathology of trauma and inflammation, microscopic as well as macroscopic. In the same way most of the anatomy of the blood vessels is quite unimportant. If an artery or vein is cut Nature will have to provide compensation, and as a general rule does, but a knowledge of the lymphatics and cutaneous nerves is most helpful. The physiology and hydrostatics of the circulation is of much greater value than the anatomical details. Muscles and their actions are tremendously important, together with the various traumata they suffer. Bones and fractures are simple compared with soft-tissue injuries, and after much inquiry I have not yet found anyone who knows anything useful about tenosynovitis, the most common of industrial diseases, and one of the most incapacitating.

And so one might go on, hacking down great forests of specialized information which are of little real value to the student. If these were removed there would be space and air for him to develop really scientific habits of observation, thought, deduction, and practice. He should be taught, as Mr. Colt says, to recognize the commoner diseases and trained to realize when he is looking at something he has not seen before. Then he should ferret it out in a book or turn to the specialist for help, or both. But he should learn to extract the most out of his clinical examination first of all. He will then begin to appreciate special tests and specialists at their true worth. All his teaching should be consciously related to the fundamental sciences such as mechanics, physics, and chemistry. Much more attention should be given to physical chemistry, which holds the clue to much that seems so mysterious, as Dr. Cooper's letter of Jan. 29 so interestingly suggested. Industry is applying it with striking results to many of the medical problems industrial processes create, and Dr. Mumford has shown us how it can revolutionize ointment bases. The whole of medicine seems ripe for reconsideration in the light of physicochemical knowledge. Through it we are likely to gain a much truer knowledge of health as well as of disease, and a clearer understanding of their difference. In view of the changing emphasis of medicine and the desire to make the doctor a health upholder rather than a health restorer, every student should know at least the elements of this science if he is to appreciate new knowledge or understand his patient and his treatment. We older ones ought to have the opportunity of learning more about it too. The same is true of nutrition and physical education.

A glance at comparative anatomy is desirable in order to place the human race firmly among the animals. Some spiritual education is also needed in order to place man equally firmly among the gods. Unfortunately the psychologists, who ought to be in charge of this department, seem so busy plumbng the depths of the Slough of Despond that they have overlooked the little wicket gate and lost track of the way of salvation. A doctor should certainly know about this, for many of his patients are as sick of mind and soul as they are of body. Then, too, we need some knowledge of sociology, even if we have to eschew a wider philosophy, in order to put our patient in right relation to his fellows and to remind us that he is a human being and not simply clinical material or an interesting (or boring) case. Last of all I think we should all profit by a study of the history of medicine to teach us the grace of humility and thankfulness, and to inspire us to carry on the torch so nobly handed down to us. If all the unessentials were ruthlessly cut out there would be ample time for the student to get a really useful knowledge of all these subjects and to realize their relevance to himself and his patient, as well as to one another. He would go out with a true education and a sound basis for further learning and experience, qualified to help his patient, able to know when he was out of his depth, knowing also where and how to get help when he needed it.

I need hardly add that it is the realization of my own deficiencies that has prompted me to make some suggestions as to how they could be avoided in others.—I am, etc.,

Winsford, Cheshire.

W. N. LEAK.

SIR,—Your correspondent Mr. G. H. Colt (Feb. 26, p. 307) is worried at the continued growth of the knowledge required for the qualifying examinations, and one readily sympathizes with him. If his solution, however, were to be taken seriously

the results would be horrifying. Are the reports received from the pathologist to have no relation to clinical medicine, or to therapeutic intentions or results? Is the radiologist a superfluity?—hardly, when one meets physicians of some standing who seem barely aware that a radiograph is a series of two-dimensional shadows of three-dimensional differential opacities, the source of rays being not even a theoretical point source, and the shadows subject to innumerable distortions depending upon the limitations of technique required for a particular examination. Is the radiotherapist to be a pure clinician with no knowledge of the lethal properties of the weapon he is using (as the practitioner who, "playing" with cineradiography, burnt a hole in his radiographer's back, or the surgeon using radium with no real knowledge of its properties and blaming the radium for the dreadful mutilations which he sometimes produces)? Or is the radiotherapist to be a pure physicist, unversed in the realm of clinical medicine? Is the physician to be allowed to practise without an intimate understanding of the pathology underlying the conditions which he is treating? Is the psychiatrist to be a layman, equipped with the results of a glorified first-aid course, who is "interested in the human mind"? Horror of horrors!

No, the answer is as straightforward as it always has been. The curriculum for the qualifying examinations must contain all, but no more than, that which is necessary for every general practitioner (or home doctor) and specialist, so that the former has a practical and reliable basis upon which to start his work, and the latter a basis—equally practical—upon which to start moulding the intricacies of his particular art, and yet maintain a true perspective of his own work in relation to the broad field of medicine as a whole.—I am, etc.,

Pinner, Middlesex.

ANTHONY A. VICKERS.

### Co-operative Research

SIR.—As an attempt to decide on the relative merits of various methods of treatment in actinomycosis, one of the undersigned suggested that it should be possible to carry out an experiment designed to give statistically sound information on these points. A statistician, Dr. Mather (author of *Statistical Analysis in Biology*), was asked to discuss the project, and as a result of the combined discussion it emerged that treatment could profitably be varied from case to case until a "block" of at least 15 cases had been treated. If these (15) cases together with other similar blocks are subjected to analysis the information we seek should be available and the reliance to be placed on it known.

Unfortunately it falls to no single hospital to get so many patients suffering from actinomycosis as would enable results to be obtained quickly, and so it was thought that it would be a sound plan to ask other hospitals to co-operate. The hope is that several hospitals which have agreed to collaborate in the scheme will agree to treat individual cases in accordance with the statistical necessities of the scheme, so that each hospital, or two or more hospitals having fewer cases, will provide a "block" of treated patients.

The scheme will require mutual discussion so as to permit all views to be considered in the final design of the experiment, and it is hoped that such a discussion can be arranged and that hospital staffs will agree to co-operate, so that at the end of one or two years we shall be in no doubt of the relative value of iodine, sulphonamides, x rays, and probably of penicillin in the treatment of this condition. Apart from any other consideration such designed experiments are desirable in clinical medicine, and co-operation such as is suggested, although a new, is not an undesirable or impossible feature.—We are, etc.,

E. C. B. BUTLER.  
FRANK ELLIS.

London Hospital.

### Blood Picture after Mepacrine

SIR,—Owing to decreasing quinine stocks the use of atebria for treatment of malaria has increased considerably, and the following observations on the blood picture after administration of mepacrine may be of interest to readers in malarial zones.

During the past three months there was a notable increase in the number of patients admitted to the maternity section of this hospital suffering from symptoms of acute malaria with

subtertian parasites in the peripheral blood. A record was kept of the results of treatment of such cases by mepacrine administered in the doses officially recommended—namely, one tablet (0.1 g.) three times daily for five to seven days. Repeated blood films were taken from all cases under treatment from the date of admission to the date of discharge from hospital nine days after delivery, and it is hoped to analyse critically in the near future the data thus obtained. Certain preliminary observations, however, appear to be of sufficient importance to justify publication of this short note.

The following observations were made on pregnant women of various races and nationalities treated with 0.1 g. mepacrine three times daily. (1) Clinical symptoms were well controlled by administration of mepacrine, and as a rule no further attacks developed after five days' treatment. (2) In a few cases disappearance of clinical symptoms after treatment was accompanied by disappearance of trophozoites from the peripheral blood. (3) In a few other cases trophozoites were present in blood films after treatment though clinical symptoms had subsided. (4) In the majority of cases administration of mepacrine in the doses stated was followed by amelioration of clinical symptoms, but blood films contained abnormally large numbers of gametocytes (crescents)—about 30 to 40 per thick film—and these gametocytes remained in the peripheral blood up to nine days after delivery.

It is well known that crescents are rarely found in the peripheral blood in tropical countries, and this observation that crescents frequently appear in the peripheral blood in large numbers after administration of mepacrine would seem to be of some importance from the epidemiological aspect. It is possible, of course, that the crescents have been damaged by the atebirin and are incapable of development in the stomach of the mosquito, but this would have to be tested in a research laboratory. The effect of plasmoquin is being studied, and a detailed report on the entire investigation will be issued later.—I am, etc.,

Public Hospital, Georgetown, Demerara.

C. ROMITI.

### Phage for Dysentery

SIR,—May I, from my remote corner over-seas, enter the lists to champion the cause of the "Goddess Phage" (as one of my grateful tea-planter patients ecstatically dubbed it 13 years ago) and to give my support to Drs. A. Compton and E. N. Russell, whose contributions on this subject in the *Journal* of June 13, 1942, and June 19, 1943, respectively (as well as those of others of contrary opinion), I have read with great interest. Like Dr. Russell, I too have marvelled that bacteriophage has not been mentioned by Col. Fairley and Sir Philip Manson-Bahr in their papers on the treatment of bacillary dysentery. Other authorities in their textbooks have made only the barest reference to it, and even then stated that it is of no proven value, etc. In India similar controversy has raged from time to time on the same subject, and last year, in a personal communication, Napier of Calcutta surprised me by saying that he did not think that bacteriophage was "much use, although some still swear by it." He then referred to sulphaguanidine as the new marvel, with which he was then experimenting on its first introduction to India.

I was introduced to bacteriophage in 1929 by Lieut.-Col. J. Morison, I.M.S., who was then director of the Pasteur Institute, Shillong, Assam's capital. Col. Morison was a pioneer of phage therapy, and he was the first to perfect its manufacture on a large scale in Assam, if not in India. In my turn, I believe I was the first tea district medical officer, on the north bank of the Brahmaputra River at any rate, to use bacteriophage for the treatment of acute bacillary dysentery and cholera. Morison's critics prophesied that the bacteriophage "bubble" would burst in 5 years' time. Time marches on, and although he has long ago retired, bacteriophage still continues to be turned out, millions of ampoules are distributed to the public all over Assam annually, and its use in controlling cholera epidemics in the Province's numerous villages as well as for dysentery is famous. The Government of India would not continue to manufacture a useless commodity on a large and expensive scale just to perpetuate the memory of Morison's "whims" or "hobby" were it indeed the case. The needs of the Army have denied all medical specialties—such as the sulphonamides—to other concerns—like the tea industry, etc.—

almost completely. We in Assam have had a fairly adequate supply of sulphapyridine, which has been very welcome, but such is the scarcity of sulphaguanidine that I received the very first supply I have ever seen only two weeks ago.

I have therefore had to rely almost exclusively on bacteriophage since the war started, and, as of old, it has stood the test of time and my faith remains unshaken. I have, like anyone else, had dramatic successes with phage as well as with sulphapyridine. I have also had some sad failures. But the successes have enormously exceeded these failures, and I have dealt with nearly 8,000 cases of acute bacillary dysentery and cholera since first I used bacteriophage in 1929. My experience agrees with what Dr. Russell reports on the preponderance of failures among infants, as well as the reasons he gives for failures generally. I have also noted that the local (Assam) bacteriophage is much more successful than, say, d'Hérelle phage or phage manufactured by firms in Bengal. I cannot pretend to explain this apparent "parochial" selectivity of phage. Many European civilians in Assam have become "phage-minded," and it is a common thing for a box of bacteriophage to be included in the luggage of many of them when travelling, especially by train, "just in case" of trouble. "Calcutta tummy" is like "Guppy tummy." While quite a few cases are known to be due to giardiasis and respond to atebirin treatment, the visitor from up-country to Calcutta often succumbs to another severe form of enteritis, and bacteriophage taken at once as a first-aid measure has often definitely prevented serious trouble. This preventive action is the great attraction of bacteriophage as well as its complete harmlessness, whereas, as Dr. Compton points out in his answer to Cmdr. Wilson (Dec. 5, 1942, p. 676), sulphaguanidine cannot be administered with impunity to provide "preventive development" to the masses, be they troops in the front line or civilians. In many villages in Assam the distribution of phage is left quite safely to the head man. This could not be done with sulphonamides.

It would be interesting to learn what the Army figures are up to date as regards the results of sulphonamide and bacteriophage treatment of troops in Assam. Finally, as everyone who has had success with bacteriophage will have observed, the cardinal conditions essential to that success are correct diagnosis and early treatment, which, of course, as Dr. Russell says, apply in any condition "from a perforated gastric ulcer to a common cold." The greatest obstacle I have ever had to overcome was the persistence on the part of many of my assistants in giving other drugs along with the phage, in spite of repeated emphatic orders to desist. It took some of them a very long time to realize that phage, and phage only, was able to cure.—I am, etc.,

Assam  
EDMUND BURKE,  
Medical Officer, Mangaldai Medical Association.

### Infective Hepatitis

SIR,—In my letter on this subject (Jan. 22, p. 130) I quoted H. Eppinger's case of "a young girl who committed suicide while suffering from 'simple' jaundice" as the case on which Eppinger based his conception that the so-called catarrhal jaundice was due to a hepatitis. My attention has since been drawn to the fact that this statement was incorrect. The facts are that during the last war Eppinger had occasion to examine the livers of four soldiers with jaundice who died from their wounds. He found no duodenitis, no swelling or plugging of the bile ducts, but the microscopical signs of what he has called later on a serous interstitial hepatitis. The case quoted by me is an earlier case (1908), and, in fact, one of the few cases observed anatomically where a swelling of Vater's papilla was found which was so marked that a sound could not be passed through it into the duodenum.—I am, etc.,

London, W.1.

H. UCKO.

According to the *Munch. med. Wschr.* for Aug. 13, 1943, the Fishery Research Station in Bergen has been working on methods of extracting insulin from fish. It has been successful in extracting from the gall of the cod an insulin which is not below ordinary standards. It is calculated that when the technique of extraction is perfected the whole Norwegian requirement of insulin will be met from the Lofoten Isles.

## Obituary

A. D. GRIFFITH, M.B., F.R.C.S.

Mr. Arthur Donald Griffith, senior surgeon to the Royal Eye Hospital, Southwark, and ophthalmic surgeon and lecturer in ophthalmology to the Westminster Hospital, died on March 5.

He was born on Oct. 20, 1882, and studied medicine at King's College Hospital after winning the Sambrooke Exhibition and a junior scholarship at King's College. He qualified M.R.C.S., L.R.C.P. in 1905, graduated M.B., B.S.Lond. in 1907, and obtained the F.R.C.S. diploma in 1909 after serving in house posts at King's and as senior resident medical officer at the Royal Free Hospital. His next appointment was that of Sambrooke surgical registrar at King's. He became dean of the School of the Royal Eye Hospital, where he had been house-surgeon, and thenceforward devoted himself to ophthalmology. During the last war he served with the R.A.M.C.(T.) in Malta, Salonika, and Italy, being mentioned in dispatches and retiring with the rank of brevet major; he also received an Italian decoration. After his return to civil life Mr. Griffith was appointed to the visiting staff of the Westminster Hospital, did good work as consulting ophthalmic surgeon to the St. David's Home for Disabled Soldiers at Ealing, and spent much time and thought in the congenial task of developing the research and teaching facilities at the Royal Eye Hospital. He was the author of a number of papers on diseases of the eye and disorders of vision published in the *Transactions of the Ophthalmological Society* and elsewhere.

Prof. ARNOLD SORSBY writes:

Arthur Donald Griffith well-nigh epitomized the ideal physician. A broad humanity permeated his personal relations; and his scrupulousness determined his professional work. To his colleagues and assistants he was a sage counsellor to whom they invariably turned for advice and guidance. Always able to see beyond the immediate tangle, his assessment of difficult situations was at one and the same time balm and positive help. Scrupulousness combined with exquisite judgment made him not merely an outstanding but the outstanding figure in any team, even if his reticence made for his comparative obscurity. The same qualities showed themselves in his work as an ophthalmologist: his diagnoses were never sudden inspirations, but the inevitable logical deductions of a meticulous examination, whilst his operations were beautiful examples of effortless deliberation. Richly endowed with that talent that is born in the stream of life, his was essentially the genius that flowers in solitude. It was for this reason that so much of his activities was little known outside the circle of those who were privileged to work with him. It is only they who know how much of the spade-work on the use of radium and x-ray therapy in ophthalmology was done by him, and only his immediate collaborators can assess how much Griffith, in his 35 years' service at the Royal Eye Hospital, contributed to the maintenance of established standards, to the aboration of new levels of achievements, and to the formulation of new aspirations. At the Royal Eye Hospital, which is perpetuating a cherished memory by a lectureship in optics, he will be remembered as a gentle colleague, a superb ophthalmologist, and a formative force in the development of research facilities in ophthalmology. His colleagues feel that a quotation from Dante, whom he loved deeply and reverently, is an apt epitaph:

"In te misericordia, in te pietate  
in te magnificenza, in te s'aduna  
quantunque in creatura è di bontate."

It is 28 years (writes Dr. WANLESS DICKSON) since I first met Mr. A. D. Griffith. We all looked to him then for help and guidance. He inspired a depth of confidence and affection few have equalled. With the passing of the years these sentiments grew broader and deeper. There was never a truer friend than "Griff," and all who knew him loved him. His passing will be a grief to a great number of his friends and associates. All at the Westminster Hospital loved him. He was tender and sensitive of heart; the sorrows of others he made his own. He was a true lover of his fellow men; a lover of animals and flowers and all the beauties of life. He was a noble, great-hearted gentleman. The attributes of Mr. Griffith's character and the logical and analytical qualities of his mind were equally well portrayed in his professional work. In his specialty he was an artist of high order. He took painstaking care in all that he did, in both clinical and operative work: "that little extra" was never lacking. He was gentle, kindly, thorough, and considerate. Life did not defeat him; to the very end he was master of his own soul. Such was Arthur Donald Griffith as we knew him, and bitter indeed is our loss and that of our profession.

We have to record with much regret the death of Dr. J. H. YOLLAND, C.B.E., who had been a member of the B.M.A. since 1896. John Horatio Yolland was born in Wandsworth in 1863, the son of a clergyman who afterwards became vicar of Hoyalake. He was educated at University College, taking the M.R.C.S.Eng. and L.S.A. in 1885. He settled down in 1889 at Bromley Common, Kent, and carried on his practice there until his death on Jan. 24. For 30 years he was on the staff of the Bromley Cottage Hospital, and also public assistance medical officer and public vaccinator for No. 1A Bromley District. He was made a life member of the Red Cross and St. John Association, and became vice-president of the Kent Branch of the British Red Cross Society. In the last war he was chief staff officer of the Kent Voluntary Aid Detachment. He held the rank of lieutenant-col. in the R.A.M.C.V., and was secretary and treasurer of the Kent County War Fund. After the war he was awarded the C.B.E. The presentation of a cheque for £250 and a silver tray in 1919 was the county's gift in recognition of his services. He received the King George Jubilee Medal in 1935. The Yolland Shield is competed for annually by Kent V.A.D.s, and another shield was given in 1912 for competition at local elementary school sports. Dr. Yolland was one of the founders of the Bromley and Bickley Golf Club, the first in the district. He was a keen lawn tennis player, and a difficult opponent to beat at croquet. From 1899 until his death he was People's Warden at St. Luke's Church, Bromley Common, and treasurer of the Parochial Church Council. The jubilee of the completion of St. Luke's fell on the same day as Dr. and Mrs. Yolland celebrated their golden wedding. A special peal of bells was also rung on Dec. 18, 1943, when the doctor reached his 80th birthday. His popularity was shown by a gathering of 400 people at his funeral; after the cremation his ashes were buried (by special dispensation) in front of the church he loved. He leaves a widow and two sons; the younger has been associated with his father in practice since 1919.

By the death of Dr. JOHN BAIRD CUNNINGHAM Edinburgh has lost one of her most respected family practitioners. Though born and educated in London, he carried out his medical studies in Edinburgh. His course was interrupted by the death of his father, which compelled him to go into his business in London for a year or two; but he was then able to return to Edinburgh, complete his medical studies, and obtain his University degree in 1913. At first he practised in Wales, and he returned there after service with the R.A.M.C. during the last war. His liking for Edinburgh, however, brought him back to that city in 1921, and he settled in the Morningside district, where he carried on a large general practice in which his thoroughness and kindness earned the confidence and affection of his patients. For several years he struggled against chronic ill-health. He was predeceased by his wife, and he is survived by a son, and by a daughter who is practising medicine in Edinburgh.

Dr. ARTHUR STANLEY HERBERT, O.B.E., formerly chairman of the Kensington Division of the B.M.A. and a member of the Council of the International Society of Medical Hydrology, died at Richmond, Surrey, on March 3. He was born at Hertford on Oct. 3, 1867, and from Hertford Grammar School went to study medicine at Guy's Hospital in 1885. He took the M.B., B.S.Lond. (with honours in surgery) in 1891, and after two house appointments at Guy's obtained the M.D. in 1892. He was for a time resident medical officer at the Royal Mineral Water Hospital, Bath, and this was the beginning of a lifelong interest in balneology and physiotherapeutics. At the close of the last century he went to New Zealand and for 17 years held the post of Government balneologist to the Dominion. During the last war he served with the N.Z.M.C. as lieutenant-col. and principal medical officer of King George V Military Orthopaedic Hospital at Rotorua. Dr. Herbert returned to this country in 1919 and settled in practice in Kensington. He was the author of *Mineral Waters and Springs of New Zealand*, 1912; *Military Physical Orthopaedics*, 1918; and *The Hot Springs of New Zealand*, 1921.

We regret to announce the death of Dr. JOHN JAMES ARMITAGE of Salisbury, who had been honorary secretary and later chairman of the Salisbury Division of the B.M.A., and in 1931-2 president of the Wilts Branch. Born at Cheltenham in 1875 son of the Rev. Arthur Armitage of Breckenbrough, he was educated at Cheltenham College and St. Thomas's Hospital, qualifying M.R.C.S. and L.R.C.P. in 1903. He obtained the M.R.C.O.G. diploma in 1938. Dr. Armitage practised in partnership at Salisbury for many years. He had been honorary assistant surgeon and medical officer to the V.D. department of Salisbury Infirmary, medical officer to the skin department, and surgeon to the maternity department, and on his retirement became consulting surgeon. He was also consulting obstetrician for the Wilts, Hants, and Dorset County Councils.

## Universities and Colleges

### ROYAL COLLEGE OF SURGEONS OF ENGLAND

#### THE DUKE OF GLOUCESTER AN HONORARY FELLOW

On March 8 the King and the Duke of Gloucester lunched with the Council of the Royal College of Surgeons at the College in Lincoln's Inn Fields. The occasion was the admission of the Duke of Gloucester to the Honorary Fellowship, and His Majesty attended in his capacity as Visitor of the College. Mr S. M. Bruce, High Commissioner for Australia, was also among those present. After luncheon the King and the Duke of Gloucester inspected the damage done to the College by enemy action and the steps now being taken towards restoration.

The President, Sir Alfred Webb-Johnson, recalled the names of members of the Royal Family who had honoured the College by accepting Honorary Fellowship; their association with the College was greatly prized and appreciated by all its Fellows and Members. Addressing the Duke of Gloucester he said that they were particularly pleased that he should visit the College before departing for Australia because they had very close associations with the Royal Australasian College of Surgeons. Its ceremonial mace was a gift from the Council of the English College, and the portrait of Lister hanging in its hall was also a present from this country; its buildings were opened in 1935 by Sir Holburt Waring, at that time P.R.C.S. Its Immediate Past President, Sir Hugh Devine, was made an Honorary F.R.C.S. in 1939, but had not been able to visit this country since his election, and the President asked His Royal Highness to hand him the diploma.

The senior Vice-President, Mr. H. S. Souttar, presented the Duke for admission as an Honorary Fellow, and the Duke in reply to the President's welcome expressed his sense of the honour paid him by the Council in enrolling him in the presence of the King. He would carry his new title proudly to Australia, and looked forward to an early opportunity there of presenting his diploma, on behalf of the Council, to Sir Hugh Devine. Conferment of the Honorary Fellowship gave him, he said, "an association with this distinguished College which I am proud to possess, and when I eventually return from the office to which His Majesty has been pleased to appoint me I shall hope for another opportunity of meeting you all again."

#### COUNCIL MEETING

An ordinary meeting of the Council of the College was held on March 9, with Sir Alfred Webb-Johnson, President, in the chair. Prof. W. E. Gye, F.R.S., was appointed Imperial Cancer Research Fund Lecturer for the year 1944. A legacy of £1,000 from the late T. P. Legg was reported. The Council expressed thanks to the President for a number of gifts, including a portrait of H.M. the King, and also to Lady Webb-Johnson for her gift of a portrait of the President.

Diplomas were granted, jointly with the Royal College of Physicians, as follows:

**DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY**—H. F. Cheadle, P. J. Devlin; C. J. Evans, J. C. Greenwood, A. Hirsten, A. Hollingsworth, Lettice M. Hughes, P. Jardine, R. L. Kerr, Monica Low, H. F. Melhuish, F. R. Neubert, R. E. Paeker, C. L. D. J. Schepers, A. S. Scott, Elizabeth D. L. Simpson, H. Treisman.

**DIPLOMA IN MEDICAL RADIOLOGY**—D. T. Burke, O. Englander, Karel Mendl, M. Sheehan, E. W. Spencer.

## The Services

Surg. Lieut.-Cmdr. J. D. Lendrum and Temp. Surg. Lieut. J. P. W. Grant, R.N.V.R., have been mentioned in dispatches for services during the action in which the *Scharnhorst* was engaged and sunk.

#### CASUALTIES IN THE MEDICAL SERVICES

*Prisoners of war*.—War Subs. Capt. M. H. Churchill, Capt. J. Hendry, War Subs. Capt. P. MacArthur, R.A.M.C.

*Missing, presumed killed*.—Prob. Temp. Surg. Lieut. M. C. Cross, R.N.V.R.

*Killed in action*.—Lieut. A. Pearlman, R.A.M.C.

#### DEATHS IN THE SERVICES

Col. EDGAR HUNT CONDON, A.M.S.(ret.), who died at his home in Exmouth on Feb. 13, was born in India in 1868, educated at Westward Ho! and Aberdeen University, and joined the R.A.M.C. in 1893, going out to India the following year. He was on active service for the greater part of the South African War and then served in India for many years, being A.D.M.S. Northern Command during the last war. On retiring in 1921 he was for 10 years in private practice at Ivybridge, Devon, and finally settled in Exmouth, where he gave valuable service as honorary M.O. to the

Exmouth Dispensary, and took charge of the gas section at the first-aid post when war broke out. Col. Condon was an excellent all-round sportsman, having won many medals for swimming in his youth, played rugger for his university, and later played tennis, golf, badminton, and billiards with marked success both in India and England. He played tennis for Wales while stationed there from 1908 to 1913. His loss is deplored by a wide circle of friends.

## Medical Notes in Parliament

On March 7 Dr. Charles Hill addressed the Parliamentary Medical Group on the National Health Service scheme proposed by the Government. On March 9 Mr. Eden announced that two days during the next series of sittings of the House of Commons would be allotted to a debate on this scheme.

#### Mental Hospital Accommodation

On Feb. 24 Mr. JOSEPH HENDERSON asked the Minister of Health whether, with a view to reducing the high death rate from tuberculosis in mental hospitals, he would consider the desirability of securing high priority for building work in connexion with mental hospitals.

Mr. WILLINK regretted that it was impracticable under present conditions to give priority to the construction of new accommodation at mental hospitals. It was also impracticable to release during the war the accommodation taken over for the Emergency Hospital Scheme or for the use of the Forces. General conditions in mental hospitals, including ventilation and dietaries, were kept constantly under review in the interests of the health of the patients. The death rate in these hospitals, though it rose at the beginning of the war, had fallen considerably. The Ministry hoped for a fall in the tuberculosis rate.

#### A National Water Plan

When Mr. Willink, on Feb. 24, moved the second reading of the Anglesey County Council Water Bill, Mr. LEVY proposed that the House should decline to do so until legislation had been passed dealing with the national water resources. He said no local authority or combination of local authorities could provide the country with an adequate water supply and drainage system unless the subject were dealt with by the Government in a national water plan. There should be a national water board and also a regional control over each watershed area. Of all commodities the nation used, two had no standard of purity. One was water and the other was milk. Thousands of dairy farmers could not get a Grade A certificate for their milk because there was no water to wash the utensils or the cattle. The Government dared not have a purity standard for water, because then nearly all the service wells would be condemned and a number of urban supplies.

Mr. WILLINK, in reply, said he would study in detail what had been said. From his first day at the Ministry of Health he had applied his mind to water supply. He had promised to introduce a Bill covering sewage in addition to rural water supplies, and he would lay a White Paper. The Government was not content with the local or with the general arrangements for water supply. Let it not go out that the water supplies in this country were a disgrace. Ninety-five per cent. of the people had a piped supply. Typhoid deaths were the lowest in the world. He hoped to put the rural water proposals before the House before Easter.

Mr. Levy withdrew his opposition and the Anglesey Bill was read a second time.

#### Compulsory Notification of V.D.

On Feb. 29 Dr. SUMMERSKILL asked the Secretary of State for Scotland whether his attention had been drawn to the resolution passed by the conference of local health authorities in Scotland urging the Government to introduce legislation to provide for the compulsory notification and treatment of venereal disease; and what action he intended to take. Mr. JOHNSTON: Yes; I have also received a report from my Medical Advisory Committee, whom I asked last year to consider certain aspects of the problem of the control and treatment of venereal diseases. That report will shortly be published as a Command Paper. I am not in a position to indicate what consequential steps will be taken.

#### National Health in Tanganyika

A debate on conditions in Tanganyika Territory took place in the House of Lords on Feb. 29. Lord CHESHAM asked the Government what steps they proposed to implement the recommendations in the report made to the Governor of the Territory in May, 1940, and pointed out that millions of natives were now existing at a very low standard of subsistence. The soil, he said, was losing fertility through lack of knowledge of good

husbandry, and the natives were content to stagnate, living on what they could produce for their own needs from the soil. As a result their physical condition had suffered, and their mental development was suffering.

Lord FARINGDON said the matter was urgent. Probably the basic problem was water. In addition to the water and the climatic difficulties, there was an amount of dust which was exceedingly injurious to health during the dry season in the highlands. In the wet districts, mist and cloud also gave rise to respiratory troubles, particularly among Europeans. The Territory was cursed with the tsetse fly and the tick. The Commissioner for the Western Province reported, with regard to the health conditions of the natives, that it had come as a shock to observe the high percentage of recruits rejected by the military authorities. It was true that the medical tests for the Army were stringent, and that many of the recruits were not the best physical specimens that the tribes could produce; but even so, it was appalling to find such a high percentage of the population graded as C3. It was a conservative estimate to say that over 50% of the men examined were rejected for military service of any nature.

The DUKE OF DEVONSHIRE said that possibly Tanganyika had been the most handicapped of all the East African Territories by shortage of man-power due to the war. After the war the entire economy of Tanganyika would have to be considered in the light of the world demands for its primary products, and no man could say what they would be. It was not possible to lay down a policy for which, at present, they could assure full continuity. The question of water resources, a general survey of which was stopped by the shortage of man-power, was again under active consideration, and plans had quite recently been before the Colonial Development and Welfare Fund for the investigation of these supplies. The Government was most anxious to see a real move forward made in the development of this Territory.

## EPIDEMIOLOGICAL NOTES

### Discussion of Table

In *England and Wales* measles continued to rise with 176 more cases, but the incidence of pneumonia fell by 116, of scarlet fever by 115, and of dysentery by 43.

The largest increases in measles were in Norfolk by 110, and in Kent by 40. In contrast to the general trend, the notifications in Lancashire fell by 79. The four counties of Kent, Lancashire, London, and Norfolk, with over 200 cases each, accounted for 52% of the total incidence of this disease. A diminution in the trend of scarlet fever was fairly general throughout the country; in Warwickshire cases fell by 27, and in Middlesex by 26.

The lowered incidence of dysentery was due mainly to the fact that in London notifications fell from 61 to 14. There were fresh outbreaks during the week in Hertfordshire 16 (Bishop Stortford U.D. 14), and Herefordshire 22 (Kington U.D. 19). The other high returns were from Surrey 37 (Banstead U.D. 17, Carshalton U.D. 10), Shropshire (Wellington U.D.) 32, Lancashire 30 (Liverpool C.B. 12), Yorks West Riding 12, Essex 12, Devonshire 10.

In *Scotland* the incidence of measles rose by 49, acute primary pneumonia by 50, scarlet fever by 43, and whooping-cough by 30 notifications—the increases in Glasgow being 35, 25, 17, and 27 respectively. The notifications of diphtheria fell by 15, and of dysentery by 62. The latter disease is still at a high level; the largest returns were from the cities of Glasgow 16, Falkirk 14, Edinburgh 12.

In *Eire* notifications of measles rose by 79, 350 of the 403 cases being notified in Dublin C.B. The incidence of diphtheria fell by 54.

In *Northern Ireland* the largest returns for scarlet fever were from Belfast C.B., 33 out of the total of 55. Londonderry C.B. reported 12 of the 28 cases of diphtheria.

### Smallpox

Since last week 3, and possibly 4, fresh cases of smallpox have occurred; all the patients were known to be contacts and were under surveillance. One of the new cases is that of a patient at Mount Vernon Hospital, where the original cases occurred. Two, sisters of a fatal case already reported, are in Finchley. The fourth and doubtful case is in Paddington. No deaths have occurred since the 3 reported last week.

### Week Ending March 4

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,997, whooping-cough 1,914, diphtheria 681, measles 1,987, acute pneumonia 983, cerebrospinal fever 53, dysentery 218, smallpox 8, paratyphoid 4, typhoid 3. The deaths from influenza in the great towns numbered 50, showing a slight rise for the second consecutive week.

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 26.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

## Medical News

The annual general meeting of the Biochemical Society will be held at the Courtauld Institute of Biochemistry, Middlesex Hospital, W.1, on Saturday, March 25, at 2.30 p.m.

The Association of Austrian Doctors in Great Britain will exhibit a medical film illustrating (1) blood transfusion, and (2) Red Army Medical Services, on Sunday, March 26, at 2.30 p.m. in the Hastings Hall, B.M.A. House, Tavistock Square. Invitation cards can be had from the hon. secretary, Association of Austrian Doctors, 14, Craven House, 121, Kingsway, W.C.2.

A reorganization of the Chinese Red Cross was effected last year by special action of the Supreme National Defence Council.

The Association of Military Surgeons of the United States has presented its Gorgas Award for 1943 to Dr. Hugh E. Cummins, retired Surgeon-General of the United States Health Service and at present director of the Pan-American Sanitary Bureau. The award was founded in 1942 by John Wyeth and Company of Philadelphia and consists of a medal and scroll and \$500. It is given each year to a member of the Association who has made "notable contributions to medical science" of value to the military service.

Dr. Bay Avni Aksel will give a lecture in Turkish on "The History of Medicine in Turkey" at the Londra Türk Halkevi (Turkish People's House), 14, Fitzhardinge Street, London, W.1, on Tuesday next, March 21, at 5.30 p.m. Sir Wyndham Deedes will translate the lecture.

The annual general meeting of the Institute of Hospital Almoners has been arranged for Friday, March 24, at 6 p.m., in the Caxton Hall, Westminster. The Minister of Health (Mr. Henry Willink) will attend and address the meeting.

The London Gazette has announced the appointment as O.B.E. (Civil Division) of Dr. R. E. Godel, senior physician of the Suez Canal Company Hospital, for services to the Army Medical Services.

The issue of the *Schweizerische medizinische Wochenschrift* for Sept. 24, 1943, was a special number in honour of the 60th birthday of Prof. Alfred Gigon, the senior editor and the founder of the Swiss Academy of Medical Sciences.

## Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Aitology* Westcent, London; SECRETARY, *Medisera* Westcent, London. ADVERTISEMENTS, *Articulate* Westcent, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

### ANY QUESTIONS?

#### Painful Spasms after Stroke

*Q.—A patient aged 79 is recovering from a recent stroke which caused mild hemiplegia. He complains much on account of muscular twitches in the limbs; the hamstrings contract in painful spasm, especially at night. Is this condition very uncommon? I have read no account of it. Is there any known treatment?*

*A.*—Detailed observation of the movements would be essential to establish their cause. The wording of the question suggests that the painful spasm may be due to degenerative changes in the extrapyramidal system, and that the patient is not suffering from a simple hemiplegia due to a lesion of the pyramidal tract. In support of this is the note that the stroke caused a mild hemiplegia. Ordinary flexor spasms, which are not usually painful, are commonly associated with more than a mild hemiplegia, although they are particularly likely to be noticed at night, when they awaken the patient. They are fired off by other movements or by stimulation of the foot. Involuntary movements of extrapyramidal origin, on the other hand, are usually quite spontaneous, are likely to have a writhing quality, and may be much more extensive or forceful than those of pyramidal

release. They range from the movements of chorea and Parkinsonism to the violent activity of hemiballismus. If this is in fact the cause, treatment at this age will be difficult, and will be confined to absence of stimulation—a warm tidy bed, sedatives and belladonna in as large doses as the patient will tolerate.

#### A Case of Low Blood Pressure

*Q.—Is there any satisfactory treatment for low blood pressure? The blood pressure of a male of 42 has been low for many years (110 mm. systolic at 26 years). Following exhausting work in 1942-3, this has now fallen to 100 mm.; and, despite prolonged rest, remains at that figure. Chief symptom—waking regularly at 3.30 a.m. (over a period of nine months) with a sensation of throbbing in the head and exhaustion, the latter persisting throughout the day. Hypnotics aggravate the exhaustion. Ephedrine and eucortin have been tried without benefit. Raising the head of the bed at night is not effective. The appetite is good and the normal amount of exercise is taken.*

*A.*—There is no indication for any treatment of the blood pressure in such a patient. Many healthy men with a systolic pressure of 100 mm. are capable of strenuous work and even hazardous war service such as flying. The symptoms described could not be due to the blood pressure, which, though lower than the average, is not too low to be normal. The whole condition as described suggests a psychoneurotic state, and investigation should be directed to this.

#### Pruritus Ani and Vulvae

*Q.—A woman in middle life suffers from intense irritation of the anus and vulva. There is no excoriation of the skin, no desquamation or redness of the parts, no threadworms or colitis. The complaint is worse at night, but often active during the day. Many things have been tried, including rectal wash-outs, ointments, and lotions. Suppositories (including morphine suppositories) have been tried. The patient is not a neurotic, and the general condition is good. What will bring relief?*

*Q.—An old lady of 83, healthy except for some arthritis, has suffered for years from pruritus of the anus and vulva. Various outside applications have given no relief. Might stilboestrol be tried in such a case, and, if so, what would be the appropriate dosage?*

*A.*—Exclude the following: other rectal or anal conditions, psychological factors such as marital unhappiness, an idiosyncrasy to aperients and other drugs, glycosuria (in first case), highly acid urine or urinary infection, trichomonas infection of the vagina, local skin disease. If the more common causes of this type are excluded and the usual local treatments have failed, then carry out a full examination of the blood and a fractional test meal. Hypochromic anaemia, with or without achlorhydria, is not uncommonly associated with "idiopathic" pruritus of the vulva, and, to a less extent, of the anus. If the findings are positive, the irritation should quickly disappear following the administration of ferrous sulphate and acid. Hydrochlor. dil., minims 10 t.d.s. Otherwise intensive treatment with vitamins A or B, and the local application of crude cod-liver oil should be tried. If all else fails a small dose of radium or x rays should be considered. In any case it is important to give hypnotics and local analgesic ointments at night to prevent the patient scratching during sleep.

Stilboestrol or other oestrogens are of value only in post-menopausal patients when the vulva and adjacent tissues are atrophic; it might be beneficial in the second case. A large dose will be necessary, so give stilboestrol 0.5 mg. or 1.0 mg. twice or three times daily by mouth. If it causes nausea or vomiting substitute oestrone 0.3 mg. to 1.0 mg. t.d.s. by mouth, and oestradiol benzoate 0.5 mg. intramuscularly twice weekly. Oestradiol and oestrone ointments can also be applied locally. The patient should be warned that such treatment may bring on uterine bleeding.

#### Weak Erection

*Q.—A patient aged 40, 3 children, has for no apparent reason suddenly developed difficulty in marital intercourse owing to weak erection. General health and habits excellent. Very fit man; no venereal disease; no excess of intercourse; no contraceptives used. The only positive finding is a varicocele of many years' standing. No psychological difficulties.*

*A.*—In spite of an apparent absence of psychological difficulties, the symptom is probably of psychological origin, and assuming that there are no abnormal physical signs, this aspect should be explored further. In the experience of the writer there is an apparent increased incidence of partial or complete impotence arising in males hitherto normal, and it is not unlikely that this is due to the strain and anxiety of present-day conditions. Quite apart from this, phases of relative impotence in otherwise normal men are much more common than is generally believed, and are associated with temporary psychological difficulties and excessive fatigue. In every case a complete history and examination are called for, to exclude neurological and endocrine disorders, but nevertheless these account only for a relatively small proportion of cases.

**Excessive Sweating**

**Q.**—A young R.A.F. officer suffers from excessive sweating under the arm-pits which ruins his tunic. Is there any remedy which can be easily applied to check this condition? The officer is quite fit and active.

**A.**—X-ray treatment should be avoided because it can only be effective when used to excess, with all the undesirable consequences of over-exposure. Temporary relief follows the application of a sponge wrung out in very hot water. Possibly one of the proprietary remedies in common use by women would be effective.

**Sex Function and Spondylitis**

**Q.**—A male aged 40 has fairly advanced spondylitis ankylopoietica, most of the lumbar, upper thoracic, and cervical vertebrae being affected. He complains of loss of sexual desire, but I find no reference to this aspect of the disease in any literature or monographs, and am wondering if spondylitis normally does affect the sex outlook, and if you could suggest any treatment that might increase sexual desire, if it is indicated in such a case.

**A.**—The possible association between the sexual organs and their functions in spondylitis ankylopoietica was referred to in an article in the *Journal* (July 3, 1943, p. 4), and I am not aware of any other observation on the subject. Probably clinical investigation is the only source from which light can be thrown on the problem, and it is one which deserves attention. Treatment by appropriate sex hormones would appear worthy of a trial, and any results, direct or indirect, should be published as a contribution to a difficult problem.

**Migraine with Deadened Extremities**

**Q.**—I would be glad to know if cure is possible in the case of a woman aged 42 who has had severe migraine since adolescence, accompanied by "deadening" of fingers and toes. On exposure to cold the fingers become white and dead. There is no evidence of arterial thickening or the permanent changes often seen in Raynaud's disease.

**A.**—Although the causes of migraine are still not known, the view has steadily gained ground that the essential abnormality is a disturbance of the autonomic control of the extracranial or intracranial blood vessels. The most favoured view associates the pain with dilatation of the pial and dural vessels, and explains the beneficial effect of ergotamine tartrate by the constriction of dural vessels which it produces. Another view ascribes the pain to vasoconstriction and explains its relief by ergotamine tartrate to the sympathetic paralysis produced by larger doses of the drug. The case described is more easily explicable along the latter lines. The interesting combination of migraine with "deadening" of the digits can perhaps be explained by assuming that the peripheral vessels in or on the nium and the extremities are alike abnormally sensitive to the action of adrenaline. The case is worthy of careful investigation. In the meantime treatment by the injection of ergotamine tartrate (0.25 to 0.5 mg.) at the very beginning of the attack should be tried. If this treatment succeeds, it would be worth while trying sublingual administration, thus avoiding the trouble of repeated injections.

**LETTERS, NOTES, ETC.****Thiouracil: A Warning**

**Dr. E. G. SLESINGER** (London, W.1) writes: The answer given under the above heading in the *Journal* of Feb. 26 (p. 313) conveys a sense of certainty and optimism not borne out by facts. Thiouracil will, it is true, reduce the basal metabolic rate to normal or below in most cases, and will therefore result in a gain in weight. Its effects on other symptoms are, however, variable. In many cases its administration leads to a marked fall in the percentage of polymorphonuclear cells in the white count, and several cases of agranulocytosis have already been noted. The statement that its administration "can be continued for many months and possibly for many years," without any warning of the need for frequent control white cell counts, is dangerous advice in the extreme. The action of thiouracil through the anterior pituitary is ignored by the writer, with the consequent occasional increase in the goitre. American opinion is gradually relegating thiouracil to a useful place as a method of pre-operative preparation. Possibly it may serve a valuable function in the medical treatment of certain types of case as well. Would it not be wise, however, to wait until controlled observations are available on enough cases before advising its general use in the light-hearted manner of your contributor and so possibly leading to unnecessary and avoidable disasters?

**Mastoiditis**

**Dr. H. HILTON BROWN** (Edinburgh) writes: I have been deeply interested in the correspondence on this subject. I do not believe that mastoiditis is ever present in the vast majority of the cases operated upon. This statement I make after having much experience of the operation, as I was clinical assistant to the late Dr. Logan

Turner in the ear, nose, and throat department of the Edinburgh Royal Infirmary in 1912 for one year. I assisted at many operations there for Dr. Turner and also the late Dr. G. S. Fraser and Dr. W. T. Gardiner, both eminent otologists. After the last war I both assisted and gave anaesthetics for the two latter for some years. So I can claim to have had the necessary experience of the operation on which to found my opinion. I personally have never allowed a patient of this practice to have the mastoid operation performed since 1919 to the present date. All ear cases have been treated at home by the parents and have all recovered. We are a practice of four partners—quite a large practice—and see very many so-called mastoids, and this is the treatment and results.

**Leucoplakia of the Tongue**

**Dr. PHILIP ROSS** (London, S.E.16) writes: I am interested in the query about leucoplakia in the *Journal* of Jan. 19 (p. 227). I have seen a few such cases caused apparently by the wearing of vulcanic dentures. In one severe case, in which all serological and other tests were negative, there was a widespread lesion on the tongue and the buccal surfaces of the cheeks, and a speedy recovery was made when the dentures were discarded. The patient was subsequently fitted with a pair made of plastic compound—hcalitic. The aetiological factors are rather obscure, but it is believed that irritation of the mouth is caused by minute electrical charges engendered by the vulcanic and "dissimilar" metals present in the pins of the plates.

**Benzyl Benzoate for Pediculosis**

**Dr. GEOFFREY DUCKWORTH** (London, W.1) writes: Regarding Dr. Blackstock's interesting account of his treatment of pediculosis capitis with benzyl benzoate (Jan. 22, p. 114), I can testify to the efficacy of a suitable emulsion of this substance for the purpose, as it has been used by several of my colleagues and myself at St. John's Hospital for Diseases of the Skin for the past two or three years. Incidentally, it is equally useful in pediculosis pubis.

**Examining School-children**

**Dr. EVA MCCALL** (Sunninghill, Berks) writes: May I join Dr. V. V. Brown (Feb. 12, p. 244) in protesting against allowing teachers to carry out any part of the medical examination of school-children? The recording of height, weight, and visual acuity should be done by school nurses before the medical inspection. The vision should, of course, be checked by the medical officer when carrying out routine inspection, and the visual defects, if any, dealt with appropriately. The school doctor, not the teacher, is surely the proper person to assess the importance of blinking, periodic squint, etc. I feel strongly that the teacher should take no part whatever in medical inspection, and that this should be carried out away from school buildings.

**An Old Midwives' Tale**

**Dr. T. P. C. KIRKPATRICK** (Dublin) writes: In the *Journal* for Feb. 19 (p. 277) you say that the "widespread popular belief that an eight-month foetus is less viable than a seven-month" is "a popular fallacy of uncertain origin." It may be of interest to note that the statement is made by Raynalde in the *Byrthe of Mankynde* (Bk. 11, c.-1), which was published in 1540, and which was taken from the *Rosengarten* of Eucarius Rosslin, which was published some twenty-five years earlier.

**Atmospheric Pollution with Cement Dust**

**Dr. D. N. STANDLEY** (Greenhithe) writes: Commenting on the letter I wrote some time ago in which I complained of the very great nuisance associated with the ceaseless outpouring of cement dust from the chimneys in this and other districts where cement is manufactured, Mr. P. G. Bowie of the Cement Manufacturers' Association stated that no dust streams out of these chimneys, but only water vapour. Obviously, we have all to learn that water vapour on condensation forms dust. I shall not waste time, yours or mine, on this matter beyond saying that everybody else is as surprised as I am to hear of such a physical phenomenon, and realize that we all have learnt something we had never heard of before. A neighbour of mine, who has seen the correspondence in the *Journal*, makes the following observation about the alleged dustless processes of cement manufacture: "In a comparative calm it is impossible to look upwards without experiencing pricking particles falling in the eyes. It is difficult to cycle or motor locally without this same experience. Gutters block up on an average every six months with grey mud. Following one day of fog at least two ounces of grey dust may be collected from any surface of about one yard square. Smoke stacks form a large mushroom top every few months. A saloon car dusts over almost as quickly as you clean it. After a spell of dry weather everything is grey with dust. Glass houses have to be cleaned with acid every year." This bears out the reality of my complaint and the need there is that it should be removed, if not while the war is on, certainly when it is over and things get back to normal again. My sole desire is not to make things unpleasant for anybody, but to voice a grievance which everybody else shares with me. This sort of thing has been going on for years. Some time or other it must end.

LONDON SATURDAY MARCH 25 1944

## SOMATIC MANIFESTATIONS OF PSYCHONEUROSIS

BY

IAN DOUGLAS-WILSON, M.D., M.R.C.P.Ed.

Capt., R.A.M.C.

A striking feature of psychoneurosis observed in the Services during this war has been the frequency with which somatic symptoms are presented. As the underlying mental disorder is usually revealed only by direct inquiry, such cases are commonly referred for investigation to the general physician. The object of this paper is to indicate how a positive psychiatric diagnosis has been reached in cases of this type without recourse to the negative exclusive method of diagnosis, which, as Cook and Sargant (1942) have pointed out, is both costly in time and money and harmful to the patient.

Of 810 patients sent for a medical specialist's opinion to a military hospital in England, 231 were diagnosed as psychoneurotic. Of this number 202 reported with symptoms referred to a particular part or to several parts of the body. Cases with organic disease have been excluded from the series except where the mental factor predominated. Psychoneurosis is taken to include anxiety state, hysteria, neurasthenia, and obsessive neurosis. The cases must be regarded as selected, because most patients with psychiatric conditions, recognized as such, were referred direct to the psychiatrist.

### Personal and Family Histories

The standards employed by Symonds and Russell (1943) in their investigation of head injuries were adopted for eliciting psychiatric histories. A history of mental disorder in close relations, of personal predisposition, or of actual previous psychiatric illness was recorded in 92% of all cases. The conditions were initiated, with one exception, without exposure to the strain of actual warfare. It is therefore not surprising that the percentage of predisposed subjects is higher than in Love's (1942) casualties at Tobruk and Symonds's (1943) cases of flying stress. The absence of personal or family predisposition was taken as an indication for redoubled caution in applying a psychiatric diagnosis. The constitutionally stable tend to develop psychoneurosis only after severe stress, the nature of which was usually elicited for the purposes of diagnosis. Some of the factors determining onset have been discussed elsewhere (Douglas-Wilson, 1943).

### Presenting Symptoms

Symptoms were presented in the following order of frequency (231 cases):

<b>Focal symptoms</b>	202 (87.4%)
Dyspnoea, palpitation, precordial pain, etc.	53
Headache	52
Respiratory symptoms	36
Abdominal symptoms	25
"Rheumatism": other motor and sensory disturbances	23
Urinary symptoms	13
<b>General symptoms</b>	29 (12.6%)
Nervousness	7
Lassitude	6
Amnesia	4
Dizziness	4
Rare symptoms	8

These figures are for the symptoms mentioned first or given greatest prominence by the patient. They do not reflect the total incidence of each group of symptoms. Combinations of two or more groups were common. For example, dizziness, though it was the primary complaint in only four cases, was a frequent subsidiary symptom, especially where the patient complained chiefly of dyspnoea, headache, or cough.

### 1. Cardiac Symptoms

The impression that the so-called "effort syndrome" is a manifestation of anxiety state has been strengthened in the last four years, though some cardiologists are not satisfied that it is entirely a psychosomatic manifestation. Wood (1941), in a careful analysis, found a family history of nervousness, insanity, or epilepsy in 56% of his cases, and noted that they showed "constitutional timidity and character inferiority."

**Personal and Family Histories.**—Of the 53 cases in this group 50 gave a positive family history of mental disorder or of personal predisposition. Sixteen were intellectually below average, and two illiterate. Thirty-one of the patients had been in civilian employment demanding little physical exertion. The three with no personal or family predisposition had all been submitted to extrinsic influences that had directed attention to the heart. One, after a long period in hospital with rheumatic fever, had received medical advice that strenuous exertion should always be avoided. The second was a man of 40 who, after prolonged sedentary employment, went on a battle course, where he was alarmed at his inability to keep up with younger men. The third was a man of 35, with a poor personality, who had done no work on account of weakness and palpitation since he had had rheumatic fever ten years previously.

**Aetiology.**—Physical and emotional stress, infection, and trauma are recognized as important aetiological factors. The induction of symptoms by suggestion through prolonged confinement to bed or by doctors' or relatives' warnings was found in 14 cases. It was noted that, whatever the reason for the patient's having been confined to bed—it varied from head injury to "nervous breakdown"—the patient himself had supposed that it was because of "something wrong with the heart." Not one of the patients that had been instructed to "take things easy" had sought further advice after the initial warning, which had been scrupulously observed in every case but one. In one case the condition appeared to be a specific response to conditions of war.

A corporal aged 49 had had palpitation, dyspnoea, and precordial pain while serving with the German Army in the First Great War. The symptoms subsided at the end of the war. After experience of a concentration camp he developed an anxiety state, but he had no further symptoms referred to the heart until he entered the British Army during the present war. The symptoms of which he had complained in the first war then recurred, though his Service employment was limited to the light work of a storeman, and he was considerably freer from physical and mental stress than he had been in Germany.

Several factors contributed to the production of the condition in some cases.

A private aged 39, with 15 years' unbroken service, reported with dyspnoea of one year's duration. His symptoms had started when he was transferred from a sedentary job to an active training unit. He said that he could run only 50 yards, when "everything went black" and he got stabbing precordial pain and palpitation. The symptoms had been worse in the last six months since a brother had been discharged from the Army owing to heart disease. A sister, killed two years previously, had had heart disease, and another brother was excitable and nervous. The patient had had a sub-average school record and, after several jobs as a labourer, had entered the Regular Army. He had liked his previous employment, in which he had apparently given satisfaction, but had not adapted himself to his new work. He had difficulty in keeping up with younger men and in learning new training: "it worries me that I will not please." He had been a bed-wetter till the age of 15, had recently had frequent sustained heavy headaches, was sleepless, and was subject to nightmares. He was depressed if not occupied, constantly recalling the death of his mother, who had been killed in an air raid two years before. He was absent-minded, had difficulty in mental concentration, and was tremulous and sweating under strain. He was unmarried, of temperate habit, and had a blameless Service record. He was mentally slow, tense, anxious, and co-operative. Physique was only fair, and he looked older than his years. There was no other evidence of organic disease.

**The Clinical Syndrome.**—The average age of the 53 patients was 31.1 years. Symptoms prior to enlistment were claimed by 25, in all of whom the condition had been aggravated by Army service. In two cases symptoms had first developed between the time of medical examination and mobilization. Particular help in diagnosis was obtained by tracing the relationship of onset and exacerbation to mental stress. In every case it was admitted that the amount of exercise required to induce symptoms varied. Dizziness, palpitation, "black-outs," and sighing for breath were further distinguishing features. Precordial pain was claimed in 42 cases, but its character seldom suggested organic cardiac disease. It was most often described as shooting or stabbing (20); less frequently as aching (7); drawing, pulling (3); cramp-like (3); and rarely as throbbing, tight, tearing, or "a strained feeling." More bizarre descriptions were given in three cases. Little help was obtained from examination of the cardiovascular system in the mild cases that constitute the majority in this series. Phobias or obsessions were admitted in 9 cases. These consisted of a sense of being gripped by the throat, associated with inability to wear anything round the neck; a feeling of suffocation in bed; an urge to breathe deeply "because no air is coming in"; and awaking with a sense of impending dissolution.

The psychiatric background in these cases has been the subject of detailed analyses (Wittkower, Rodger, and Wilson, 1941). The personality types most often encountered in this series were: (1) the immature, dependent type, usually querulously hypochondriacal; (2) the aggressive, resentful subject, who speaks defiantly of "my leaking valve" and resists reasoned reassurance; (3) the patient of inherently unstable temperament, with marked predisposition or actual previous history of psychiatric illness; (4) the artistic, "highly strung" man, with little liking for or adaptability to Service life; (5) the constitutionally stable type, who develops cardiac symptoms as an isolated manifestation after gross physical or emotional stress or after strong extrinsic direction of attention to the heart: in the Army, the most striking example of this group is the soldier of 35 to 40 who is called on to undertake strenuous training alongside younger men.

## 2. Headache

One hundred and thirty-one, or 57% of all cases, reported the presence of headache. This was described as heavy (34), pressing (32), aching (22), tight (12), throbbing (11), beating (5), shooting (5), tugging (3), and numb (2). Bizarre descriptions were given in five cases. The pain was said to last for many hours or days with little variation in intensity, or to come on in the mornings and to pass off about midday. It was sometimes aggravated by exercise, worry, excitement, heat, or a visit to the cinema. Partial relief was sometimes admitted by holding the head, mental diversion, and aspirin. In other cases no aggravating or relieving factors were recognized.

Twenty-seven of the 52 men with headache as the primary complaint dated their symptoms from previous head injury. It

is noteworthy that 11 of these were intellectually dull. These patients, even more than those complaining of headache without previous trauma, were preoccupied with the condition of their heads, and, in particular, with the possibility of further head injury. Two had made complete recoveries from severe head injuries and, after further trivial trauma, had developed gross psychoneurotic states with persistent headaches.

Of the 25 patients who had not been injured only two were intellectually below average. The development of headache as an isolated symptom of anxiety was recorded in four patients of conscientious type and excellent intelligence.

A padre in the middle thirties, who had been with a division that had seen much fighting, reported with unremitting pressing headache. He had been troubled by conflict between a sense of obligation to return to his division and fear that he might not continue under battle conditions to show the example that he felt was due from him.

Patients complaining of headache are sometimes preoccupied with fears of insanity or brain tumour. Dizziness and "black-outs" are common associated symptoms. The "black-out" is described as "a mist coming over the eyes" or as "a curtain drawn over the eyes."

## 3. Respiratory Symptoms

The complaint in each case of this group, whose average age was 29.9, was cough. No case has been included in which there was any abnormality on routine physical and radiological examination, and, in particular, cases of asthma have been excluded. There is no basis for regarding cough as either an expression of hysteria or a manifestation of vegetative neurosis. It is probable that some degree of tracheitis was present in each case. That tracheitis is prevalent in the Army is suggested by the questioning of 100 healthy controls, of whom 62 reported a persistent "smoker's cough."

The most frequent factor determining the patient's preoccupation with his chest was found to be family or personal experience of chest disease. Eighteen of the 36 cases gave a family history of tuberculosis in parents or siblings, and admitted to fear of this disease. Eleven others had had previous serious chest disorders, such as pneumonia. The cough was typically present throughout the year, with little seasonal or diurnal variation. A small amount of sputum was said to be expectorated. Some patients, especially those who had witnessed tuberculosis in their families, claimed loss of weight, night sweating, and even haemoptysis. Pains in the chest were reported in two-thirds of this series: it was described most often as tight, aching, or shooting; rarely as burning, searing, or heavy. Gross dyspnoea on exertion was reported in all except two cases. One of these had previously had pleurisy and feared tuberculosis. The other, as well as cough, had stabbing precordial pain and palpitation, and was alarmed at the possibility of heart disease, of which his mother had died. Twelve patients, in addition to dyspnoea, had other symptoms related to the heart. Of these, two, though their initial complaint was of cough, later admitted preoccupation with the possibility of heart disease.

## 4. Abdominal Symptoms

The true proportion of psychoneurotics presenting abdominal symptoms is not reflected in this series, as abdominal cases were mostly seen at a separate clinic, experience of which suggests that the syndromes presented fall commonly into one of these groups:

(a) The patient complains of vague diffuse pain, the site of which is indicated by sweeping the hand across the upper abdomen. It may be described as aching, burning, sharp, or heavy. It often dates from youth, is unremitting, and is progressive only from entry into the Service, this progression being attributed to "greasy food." It is constant throughout the day, but does not interrupt sleep. It is worse after meals, and alkalis provide, at best, only partial relief. Flatulence is prominent, and vomiting after all meals may be reported. The bowels are usually constipated. A family history of gastric disorders is forthcoming in half the cases. Examination shows no recent loss of weight. There is diffuse upper abdominal tenderness without special localization. Acrophagy may be witnessed, and, in hospital, vomitus is found to consist of a mouthful, or two of fluid regurgitated soon after meals. Temporary relief may be obtained by dieting, but, as Tidy (1943) has pointed out, relapse occurs as soon as the patient is discharged from hospital.

(b) The patient presents a group of symptoms that are compatible with peptic ulceration. The barium meal shows a hypertonic active stomach, and the fractional test meal may reveal hyperchlorhydria.

(c) The patient reports on account of constipation, lenteric diarrhoea, or griping lower abdominal pain. A spastic colon may be palpated.

(d) A bizarre picture is presented. An officer aged 32 gave a five-months history of constant unvarying nausea and "sense of apprehension" in the umbilical region. It was found that the symptoms had begun when he heard that his wife was pregnant.

### 5. "Rheumatism"; Other Motor and Sensory Disturbances

Twenty-two patients reported with muscle or joint pains. The localization of pains in five was accounted for by previous trauma or operation. Of the remainder, the factor determining localization could be detected in only one case—that of a patient, aged 41, who had had "a clawing feeling" and sense of coldness in both knees for nine years, since the doctor treating him for gonorrhoea had said that rheumatism might ensue as a complication. In the other cases pain was described as being in either muscles or joints, and was said to be constant and often symmetrical. It was most commonly aching, less frequently shooting, numb, pulling, cramp-like, or "a flushed feeling." Associated weakness was found in only one case, and no disturbance of cutaneous sensation was detected. Two patients who reported with lumbar pain admitted to preoccupation with the possibility of tuberculosis, of which there was a family history in each case.

One man, aged 31, with gross variable tremor of the right upper limb, reported that this had been present since a blow in the mid-thoracic region of the back at the age of 12.

### 6. Urinary Symptoms

The 13 patients reporting with urinary symptoms were juvenile immature types who particularly missed their home environments. Seven patients, five of them grossly dull and backward, reported nocturnal enuresis from infancy. All had noticed recent aggravation of the symptom. This was attributed by five to self-consciousness under Service conditions: one had noticed exacerbation since he had married, and the last dated the increase from the incidence of business worries. Six cases reported the recent onset of frequency, three of these having also recent nocturnal enuresis. Four of these patients were mentally dull. The onset in three had been associated with fears of venereal disease following exposure to infection. In the other three the symptoms had begun on enlistment, which had been associated with concern about separation from families. One of these patients, aged 39, gave a story of regular and classical migrainous attacks from enlistment two years previously. These simulated exactly the migraine to which his wife had always been subject.

### Discussion

Patients in this series, although their symptoms were predominantly somatic, readily admitted, on direct questioning, to concomitant mental manifestations. Where the onset was recent they quickly gained insight into the psychological origin of their condition. This coincides with the experience of Gillespie (1941) and others that the so-called "war neuroses" arise at a superficial level and seldom result in permanent personality changes.

Symptoms often coexisted in more than one system. For example, 81 of the 178 cases that did not primarily claim cardiac symptoms reported, as subsidiary complaints, dyspnoea, palpitation, or precordial pain. It appears undesirable that psychoneurotic states should be classified into such categories as "effort syndrome," because such grouping focuses unwarranted attention on a single aspect of the condition and, as Hyland and Richardson (1942) have pointed out, tends to obscure consideration of the underlying personality disorder.

Evidence of personal predisposition or a history of psychiatric illness in close relatives was found in most cases. Important factors determining the localization of somatic symptoms were existing trivial organic disorders; previous personal or family history of organic disease in the affected system; and recall of earlier warnings by doctors and relatives about the condition of the system involved. In some cases with cardiac symptoms prolonged confinement to bed had fixed attention on the heart; while in others the strenuous Service life had contributed to the localization. In most cases where a factor determining localiza-

tion was found, the patient admitted to fear of organic disease. The patient did not always refer symptoms to the system in which disease was feared.

In the remaining patients no factor determining localization could be found. These mostly had symptoms that were directly attributable to autonomic imbalance, such as "hypertonic gastritis" and frequency of micturition. It appears that revision of nomenclature is necessary to differentiate such "functional" conditions in which there is definite physiological disturbance, from those in which physiological disturbance is absent or unproved. This could best be effected by discontinuing the use of "functional" to describe either type.

The manifestations of anxiety state are now generally attributed to dysfunction of the sympathetico-adrenal reflex. More speculative psycho-analytical work suggests that the site of symptoms is conditioned by profound mental factors, the physiological response varying with different emotional tensions (Alexander, 1943). Whatever the ultimate cause, there can be little doubt that the immediate cause is organic, because, whatever the system affected, the symptoms tend to conform to fixed patterns. Divergence from these patterns suggests that the condition is attributable to hysteria or that the symptoms of vegetative neurosis have suggested to the patient hysterical features which have been superadded.

### Summary

The presenting symptoms in 202 cases of psychoneurosis reporting with somatic manifestations have been analysed. Predisposition to mental disorder was found in nearly all cases.

Important factors determining the localization of symptoms were found to be family or previous personal history of organic disease in the system involved and existing trivial organic disorders.

Cardiac symptoms had been suggested to some by long confinement to bed or by warnings to avoid exertion. In others, the energetic Service life had directed attention to the heart. In several, more than one extrinsic factor had produced the condition. Associated phobias were sometimes present.

Chest symptoms were commonly associated with fear of tuberculosis, of which there was a family history in half the cases. Gross dyspnoea was the rule.

Headache was seldom of a type that suggested organic disease. The patient was often preoccupied with the possibility of brain tumour or insanity, and—where the condition followed head injury—with the possibility of further trauma.

Abdominal symptoms, except when due to hysteria, tended to conform to one of three groups of symptoms. In some there was definite physiological disturbance.

Urinary symptoms were reported by patients of immature and dependent type.

Somatic manifestations, when due to anxiety states, usually conform to definite recognizable patterns. Symptoms often coexist in more than one system.

I wish to express my thanks to Col. M. J. Williamson, M.C., for permission to submit this paper. I am indebted to Wing Cmdr. Denis Williams for much helpful advice.

Last July tens of thousands of contributors to the Hospital Saving Association decided to mark the 21st anniversary of their Association by a free-will offering of thanks to hospital nurses. They raised £12,000, which will be devoted to providing much-needed scholarships. These will be awarded annually over the next four years as follows: two scholarships for nurse students of £250 each, four for nurse teachers of £200 each, four for health visitors of £100 each, twelve for industrial nurses of £65 each, and four for midwife teachers of £75 each. The Rushcliffe report brought some improved conditions for nurses, but the proper training of new entrants will still depend upon competent teachers. H.S.A. scholarships will go a little way to securing these teachers and may stimulate others in the provision of postgraduate educational facilities.

# LUNG ABSCESS IN RELATION TO THE INFLUENZA EPIDEMIC

BY

ELI DAVIS, M.D., M.R.C.P., M.Sc.

Deputy Medical Superintendent and Physician, St. Andrew's Hospital (L.C.C.)

In the fourth week of Nov., 1943, the influenza wave impacted upon St. Andrew's Hospital. Some forty days later influenza admissions dropped abruptly. During this period 5 cases of lung abscess (3 fatal) were seen among 17 patients aged 12 to 60 with influenzal pneumonia. They are described below. Of the 12 other patients, 2 died, and one of the latter cases (on which a necropsy was done) is also described. Results of sputum cultures and white cell counts are given in the Table.

## Summary of 6 Cases of Influenzal Pneumonia, 5 with Lung Abscess

Case No. and Outcome	Bacteria in Sputum	Site of Abscess
I: Recovery	Staph. aureus (pure culture)	Right upper lobe
II: Death	Staph. aureus; H. influenzae; haem. strep.	Left "lower" lobe; left eye
III: Recovery	Staph. aureus; H. influenzae; pneumococcus	Right upper lobe
IV: Death	Staph. aureus; pneumococcus	Right middle lobe; right brain
V: Death	Haem. strep.; H. influenzae	None
VI: Death		

At the height of the disease the white cell counts ranged from 11,000 to 18,300 per c.mm., with polymorphonuclears around 80%.

### Case I

A housewife aged 38 was admitted with pneumonia of the right upper lobe, following influenza two weeks earlier. There was no response to full doses of sulphathiazole, and within 48 hours of admission radiological evidence of abscess of the right upper lobe was seen. She coughed up 2 oz. of slightly blood-stained purulent sputum daily, mostly after postural drainage. After four weeks of acute illness in hospital, with a temperature swinging between 99° and 102° and a pulse rate of 100 to 128 a minute, she began to recover steadily. Her serum contained no antibody for psittacosis antigen (Prof. S. P. Bedson) and no cold agglutinins.

### Case II

The illness of this patient, a labourer aged 40, began with dizziness and collapse five days before admission. There followed pain in the chest, cough, and scanty sputum but no haemoptysis. When seen he was panting and cyanosed; temperature 101.4°, pulse rate 92, respirations 32 a minute. He was regarded as a case of influenzal bronchopneumonia, with the right lung more involved than the left. There was heavy albuminuria. He died in 48 hours, having had 18 g. of sulphapyridine, oxygen, and nikethamide. At necropsy the right lung showed confluent bronchopneumonia, with numerous abscesses 0.5 cm. in diameter in the anterior half of the upper lobe, collapse at the base of the lower lobe, and purulent bronchitis. There was right serofibrinous pleurisy, with 15 oz. of pleural fluid. The left lung showed oedema and congestion only.

### Case III

In this case, that of a lorry driver aged 33, influenza began one week before admission and was followed by rigors, cough, and scanty rusty sputum. On admission he had left basal crepitations. Temperature 100.8°, pulse 112, respirations 28. Severe left uveitis developed in two days, and blisters on his fingers 24 hours later. The left eye became more and more inflamed until there was a panophthalmitis. Sulphapyridine was given in full doses from admission and sulphacetamide was applied to the eye, but without benefit. The left eye was removed on the 12th day of the disease by Mr. M. Shaw. A radiograph on the 15th day showed an abscess of the left lower lobe. Temperature and pulse settled on the 24th day, and there was steady improvement thereafter, with natural healing of the abscess.

### Case IV

A labourer aged 57 had suffered from chronic bronchitis for years. He collapsed one week before admission, and cough with yellow sputum developed. When admitted he showed marked cyanosis and dyspnoea, general bronchitis and right bronchopneumonia; temperature 99.4°, pulse 132, respirations 32. He seemed to respond

to sulphapyridine, the fever subsiding quickly and the temperature remaining down while on sulphapyridine (25 g. given) and for a further 60 hours. The temperature then rose again and ranged from 98° to 103°. On the 23rd day of the disease the sputum became bloody and treacly, and abscess of the right upper lobe was diagnosed and confirmed by x rays. He coughed up 14 oz. of sputum daily, mostly in the morning, after postural drainage. His temperature settled (spontaneously) on the 43rd day of the disease, but his general condition deteriorated, and he died afebrile on the 46th day. Necropsy was refused.

### Case V

A female munition worker aged 20 was taken ill 5 days before admission with a rigor, tightness behind the lower sternum, and slight cough with scanty sputum. On examination she presented a toxic aspect, and had a few crepitations over the right anterior axilla; temperature 103°, pulse 120, respirations 24. The temperature dropped abruptly after 6 g. of sulphapyridine, but rose again, gradually at first, despite continuing with the drug. By the time 25 g. was given the temperature had reached 104°. Sulphapyridine was stopped. Fever continued swinging from 100° to 104° for the next ten days. Rales became numerous at the right base. The patient insisted that she "felt fine." A drachm or so of nummular sputum was coughed up daily, and was haemorrhagic only once. On the 21st day of the disease tinkling rales were heard over the right mid-zone, and lung abscess was considered. Rales were also heard over the left base. Sulphamezathine therapy was begun; but by the 23rd day deterioration was pronounced, with drowsiness, contracted pupils, and bilateral papilloedema. The cerebrospinal fluid was turbid with masses of polymorphonuclears, but no organisms were grown from it. Sodium sulphadiazine (5 g.) was given intravenously, and was repeated next morning, in addition to oral sulphamezathine. She died on the 25th day of the disease.

**Chest Radiographs.**—On the 9th day of the disease x-ray films of the lungs showed no abnormality; on the 15th day there was a right hilar shadow (later proved to be due to lung abscess), with surrounding pneumonia. Blood culture was negative.

**Necropsy.**—There was muco-purulent bronchitis. The right middle lobe showed grey consolidation. Anterior to this grey area was a superficial acute abscess 5 by 4 by 4 cm., extending nearly to the midline behind the sternum. There was a spread of pus to the mediastinum above the base of the heart, with two small secondary abscesses here, near enlarged lymphatic glands. Intense congestion, collapse, and recent bronchopneumonia were observed in the right and left lower lobes, and recent fibrinous pericarditis. The spleen was moderately enlarged, congested, and soft. In the brain were two superficial acute abscesses, 2.5 cm. in diameter, containing green pus—one in the right temporo-parietal region, and one in the right occipital region, with purulent basal meningitis. The middle-ears were clean. The pus from the brain abscess grew a pure culture of haemolytic streptococci, although the organisms from sputum culture were *Staph. aureus* and pneumococci.

### Case VI

A housewife aged 56 gave a history of two attacks of influenza in the previous month. The second attack began two weeks before admission and was followed by cough and chest pain. On examination there were signs of left basal consolidation and right bronchopneumonia. The temperature (99.6°) soon subsided with sulphapyridine therapy, and by the time 22 g. had been given had been normal 48 hours. The drug was stopped, but the temperature rose again, and continued to swing between 99° and 101°. She coughed up 1 oz. of blood-stained sputum daily. The lung signs persisted, and she deteriorated, dying on the 19th day in hospital. She had been given sulphamezathine for the last 36 hours of life.

**Necropsy.**—There was a diffuse, coarsely granular consolidation of all lobes of both lungs and dense diffuse fibrosis of the bases. The appearances suggested unresolved pneumonia on a previously fibrotic lung, and this was confirmed histologically. There were recent bilateral fibrous pleural adhesions. The spleen was twice the normal size, oedematous, congested, and soft.

### Discussion

Influenzal pneumonia was diagnosed on clinical grounds. The disease began in most of the patients with the features characteristic of the influenza prevalent in the neighbourhood—fever, malaise, generalized aches and pains, and cough with scanty sputum. When pneumonia developed the temperature was not initially as high as in lobar pneumonia, but fever was more prolonged. Physical signs were not clear-cut. White cell counts were essentially the same as in primary lobar pneumonia. The sulphonamides had no obvious effect in at least 12 of the 17 cases. The remaining 5 cases cleared up well concurrently with the administration of sulphonamides.

It is conceivable that complications and mortality would have been greater but for the sulphonamides, but I do not think so.

The 17 patients considered in this paper were aged 12 to 60. Pneumonia in infants did not differ essentially from the cases I saw in the previous year. Many chronic bronchitis over the age of 60 who would almost certainly have died during the winter from bronchopneumonia and congestive heart failure had death precipitated by influenza. Of the 17 cases, 12 recovered. Recurrent epistaxes were prominent in one boy, another patient had haemorrhagic vesicles of the inner cheeks, and one had a small pleural effusion. Pneumonia was bilateral in 4 patients. Before the epidemic proper began, 2 cases of influenzal pneumonia were seen—a fatal case in August on which a necropsy was done, and one in mid-October which recovered.

It is of interest to compare this experience of influenzal pneumonia with 5 deaths and 5 cases of lung abscess (and *Staph. aureus* the chief organism concerned) with recent experience of lobar pneumonia. From Oct. 1, 1942, to Dec. 31, 1943, I saw 107 consecutive cases of primary lobar pneumonia, the ages ranging from 5 to 65. There were 2 deaths, and 2 cases of lung abscess with recovery. From Jan. to Oct., 1943, I saw 13 cases of primary atypical pneumonia (one with rising titre of psittacosis antibody—Prof. Bedson), but none since. It is tempting to inquire if there is any relation between the recent frequency of primary atypical pneumonia and the influenza epidemic.

Concurrently with the influenza epidemic, primary lobar pneumonia became much more frequent here: 26 patients aged 5 to 65 were seen in 40 days, with one death. It may be that a number of these cases were really influenzal pneumonias, but there was not enough clinical evidence for so regarding them.

#### Summary

In the recent influenza epidemic, among 17 cases of influenzal pneumonia—ages 12 to 60—there were 5 deaths. There were 5 cases of lung abscess (3 fatal), and one patient who recovered had a metastatic panophthalmitis. *Staph. aureus* was an important invader. Sulphonamides were not beneficial. In 107 cases of primary lobar pneumonia—aged 5 to 65—there were 2 deaths, and 2 cases of lung abscess with recovery.

I thank Mr. J. R. M. Whigham for his encouragement; and Dr. C. Illiard, radiologist; Drs. A. B. Rosher, A. B. Bratton, and C. C. Bryson, pathologists; and Drs. R. Gross-Heisler and S. Gee of the medical team, for their help.

## PROGNOSTIC VALUE OF LABORATORY INVESTIGATIONS IN TYPHOID FEVER

BY

S. S. BHATNAGAR, M.D., Ph.D., F.R.C.P.

Lieut.-Colonel, Indian Army Medical Corps

(From a Combined Indian General Hospital, India Command)

Laboratory investigations in typhoid fever are usually employed for the confirmation of clinical diagnosis, either directly by the isolation of the infecting organism from blood, urine, or faeces, or indirectly by the estimation of antibody production, chiefly Vi and O agglutinins, as proof presumptive of the presence of *Bact. typhosum* in the human body. In military hospitals in India blood cultures in the early stages, agglutinations throughout the course of infection, and collection of evidence for the excretion of micro-organisms, even during convalescence, comprise the routine procedure for such cases. The analysis of collective results so obtained, in conjunction with clinical observations, indicated that the various combinations of signs and symptoms met with in this disease were associated with distinct variations in laboratory findings, the study of which was of considerable prognostic significance. Not only was it thus possible to gain an insight into the ups and downs of the struggle between host and parasite, but specific antityphoid serum therapy, practised in a large number of cases (to be presented in a subsequent communication), could also be placed on a more satisfactory basis.

The object of this paper is to describe and discuss the prognostic inferences drawn from a study of 280 cases of typhoid fever in which laboratory investigations were carried out at short intervals throughout the course of infection. Reference is made to certain aspects of the diagnosis and prophylaxis of typhoid that are directly related to the observations recorded here. For reasons of space tables and charts are not included.

The whole group of cases has been subdivided into six different clinical and bacteriological identities. Although some overlapping of symptoms, rather than of signs, was noticeable between the various subgroups, it was not extensive enough to confuse the main issues.

### Clinical and Bacteriological Types of Typhoid Cases

1. *Simple Type*.—These cases presented the textbook description of the disease, with temperature which followed the course of three well-known stadia—*incrementi*, *acmes*, and *decrementi*. The total duration of pyrexia varied from 10 to 25 days, depending upon the inoculated state of the individual. In a person who had had multiple injections of T.A.B. vaccine—prepared in a reliable institution with appropriate strains of *Bact. typhosum*—all the stages were completed quickly, and the patient looked so well towards the end of the second week that, in the absence of laboratory diagnosis, doubts could be expressed as to the nature of the infection. Such cases were usually met with among military personnel with more than six years of colour service. In the uninoculated pyrexia was prolonged until the fourth week. In both types of individuals, however, the entire course of the disease was free from complications. Bacteriologically, blood culture was usually negative, since bacteraemia in such cases was of short duration. Agglutination tests, on the other hand, were most satisfactory, and of the type commonly designated as "Widal-positive"; the O titre was about 200 and the Vi agglutinins were as described in a previous communication (Bhatnagar, 1938). It was easy to isolate the infecting organism from urine or faeces, or both, during the second, third, or fourth week. The strain isolated was agglutinable by both O and Vi sera, and its average lethal dose (a.l.d.), for white mice weighing from 20 to 22 g., was more than 100 millions—the V-W type of organism described by Kauffmann (1935).

2. *Ambulatory Type*.—These cases represented the other extreme of the prognostic picture in that they were invariably fatal. Before the patient was obliged to seek admission to a hospital or take to bed properly, he had been definitely ill for over a week. The case below illustrates the various points:

A robust, healthy man, 28 years of age and 14 stone in weight, was feeling seedy for about 10 days before admission to hospital. During this period he took aspirin and quinine regularly to enable him to carry out his duties. He was ultimately obliged to stay in bed. On admission enteric was suspected, and in spite of careful nursing and efficient palliative treatment his condition deteriorated. On the fifth day he complained of pain in the lower abdomen. Clinical examination revealed perforative peritonitis. His general condition was, however, so bad that any surgical intervention was ruled out; he died a few hours later with a rectal temperature of 110° F. Necropsy revealed typical typhoid ulcers in the small intestine.

Laboratory investigations in such cases were most disappointing: they presented a completely negative picture—so much so that the reliability of clinical diagnosis was questioned on more than one occasion. No Vi agglutinins were detected at any stage of the disease, although in some cases the O antibody titre could be considered to be suggestive of typhoid infection. Diagnosis could be confirmed post mortem only by direct culture from inflamed Peyer's patches, spleen, gall-bladder, and bone marrow. In the few cases in which this facility was available it was particularly observed that the growth of *Bact. typhosum* on first isolation was scanty and the strain of only average virulence—a.l.d. more than 100 millions, and the organism agglutinable by both O and Vi sera.

3. *Toxic Type*.—These cases were usually seen either among the civilian population or among military personnel—such as drafts arriving from over-seas—who had not had the benefit of multiple T.A.B. inoculations. The patient was clinically toxic before the end of the first week of illness; the skin

was dry and the tongue dry and deeply furred. There was general clouding of intellect; and the mental processes varied from simple slow cerebration to general apathy or, conversely, marked delirium. Usually there was no localized involvement of any particular organ, but haemorrhage from the bowels occurred in a number of cases. The most characteristic bacteriological feature was an abnormal rise in the titre of O agglutinins with no evidence of Vi antibody formation. In this series the O titre varied from 2,000 to as much as 20,000. Blood culture was usually positive during the first week, but no excretion of organisms could be detected in later stages. In cases which ended fatally this held true and the high titre of O agglutinins was maintained. On the other hand, in those who recovered, either naturally but more often through serological intervention, some remarkable changes took place in the bacteriological picture within as short a period as 24 hours. There was a sudden drop in O titre to normal proportions (200–500), with simultaneous appearance of Vi antibody accompanied by what may be termed a flooding of both urine and faeces with typhoid bacilli. The strains isolated were fully virulent, inagglutinable by an O serum, but easily clumped by a Vi serum with an a.i.d. of less than 100 millions—the V type of organism described by Kauffmann (1935).

**4. Prolonged Pyrexia (P.P.) Type.**—The duration of pyrexia in such cases varied from 6 to 12 weeks. During this prolonged course the temperature showed a tendency to drop to normal on more than one occasion; but these oscillations could be easily distinguished from true relapses in that the temperature did not stay at normal longer than from 24 to 48 hours. Such cases were usually free from complications, the only complaint being "fever" for which causes other than typhoid infection—especially *B. coli*, pyelitis, and pulmonary tuberculosis—were looked for with negative results. The diagnosis was easily established by a positive blood, urine, or faeces culture. The characteristic feature was either a complete absence or a very low titre of Vi antibody. So long as Vi titre did not improve, the fever continued. It was only when this antibody developed, either naturally or by artificial introduction into the system through serum therapy, that the host got the better of the parasite and infection terminated. The micro-organism isolated was easily agglutinable by both O and Vi sera with an a.i.d. of more than 100 millions.

**5. Embolic Type.**—The predominant feature of these cases was the abnormal localization of the infecting organism in one of the organs—chiefly lungs, meninges, or intestine—resulting in bronchopneumonia, specific meningitis, or a severe form of melaena respectively. The clinical picture is commonly referred to as complicated typhoid fever. The course of infection was unduly severe and the mortality heavy. There was no evidence that the condition was metastatic in origin, the term "embolic" being applied only for descriptive purposes. The infecting organism was isolated from the peripheral blood with ease not only in the early stage but also during the second and third weeks if the patient lived. There was considerable excretion of bacteria via both the kidneys and the intestine; and in certain cases the unusual picture of blood, urine, and faeces all being positive at the same time was encountered. Serological tests, on the other hand, were disappointing, there being complete absence of Vi antibody with little rise in O agglutinins. The strain of *Bact. typhosum* isolated was highly virulent, with an a.i.d. in the region of 60 to 80 millions, inagglutinable by an O serum but reacting to Vi antibody.

**6. Relapse Type.**—During the course of typhoid infection relapses occur in a certain percentage of cases. Clinically there are no means by which we can assess the possibility of such an event taking place. Laboratory investigations, however, suggested that certain unusual occurrences should arouse suspicion about the possibility of a relapse—namely: (a) a positive blood culture during the third week where previous cultures had proved sterile; (b) a positive blood culture with the temperature on the down grade; (c) a fall in the titre of Vi agglutinins in the third week without a similar simultaneous effect on temperature; and (d), conversely, the maintenance of a high Vi titre with temperature showing a normal tendency.

## Discussion

To appreciate the prognostic significance of the variations in laboratory findings in different types of clinical manifestations of typhoid fever it is necessary to take into account the part played by Vi antibody in typhoid immunity as described by Felix and his co-workers—for references see Topley and Wilson (1936). In our experience the presence of this antibody in a sufficiently high titre (50–250) always connoted a satisfactory outlook. If this antibody was present early in the disease and the high titre was maintained over a number of days it could be predicted with confidence that the course of infection was going to be short and the patient on the road to convalescence by the third week. Such cases are included in the *simple type* of infection described. They formed a large component of a previous communication on the value of Vi agglutination in typhoid fever, to which reference has already been made.

We have no record of a case in this series in which a high Vi agglutinin titre was associated with such fulminating symptoms as are included under the *embolic type* of infection, although 73 cases of this nature were studied. The Vi antibody was either completely absent or, if detected, the reading was seldom higher than 10–20; even this low titre was not maintained, and it appeared only spasmodically. If the case was to end fatally there was no rise in Vi agglutinins. On the other hand, in the few cases that recovered naturally—only 4 out of 73 in this group—the improvement in the clinical condition was preceded by an elevation of Vi titre. In two of these, with lung involvement, Vi antibody developed suddenly and a high titre (80–160) was kept up for 11 days. The lung condition cleared and the patient recovered after prolonged convalescence. In the other two, with bowel haemorrhages, the Vi titre dropped from 160 to 20 within 3 days, with a concurrent fall of temperature to subnormal. Both these cases relapsed—on the fifth and the sixth day respectively, with one and two similar relapses subsequently—before a sustained Vi antibody titre was elaborated naturally and the infection was eventually overcome on the 79th and the 88th day of disease.

Study of the *prolonged pyrexia (P.P.) type* of infection lent further support to the role of Vi antibody in the pathogenesis of typhoid fever. Nineteen such cases were observed. Clinically, everything was in the patient's favour, especially his general condition and the freedom from complications. The fever, however, continued for weeks. It came to an end only when a sustained Vi titre was recorded, either produced naturally or provided by specific serum therapy.

An abnormal rise in O agglutinins was seen to be associated with the *toxic type* of case, the titre of this antibody in different cases varying from 2,000 to as much as 20,000. In none of the other types of typhoid fever cases was this high reading encountered, nor was it experienced in their treatment with either Felix or convalescent serum. In view of the high mortality in this group—15 out of 27 cases studied having proved fatal—and the fact that recovery was always preceded by a considerable drop in the O titre of serum, the high rise in O agglutinins must be considered to be pathological, since its prognostic interpretation is directly opposed both to the generally accepted clinical concept associating O antibody production with favourable prognosis and the immunological observation that the O titre of a serum expressed its protective value in relation to endotoxins. As all the cases were highly toxic the possibility of abnormal O-antibody production becoming associated in some unknown manner with toxin liberation; rather than being responsible for its neutralization, cannot be ruled out, although there is no experimental evidence to support this view. It will also be seen from the observations recorded that O antibody is not concerned in the excretion of typhoid bacilli from the human body, since none was found to take place while the high titre lasted.

Of the *ambulatory type* 32 cases were under review. All of them were characterized by: (1) absence of complete rest during the first week after the signs and symptoms associated with the early stage of typhoid fever had appeared; and (2) the employment of antipyretic drugs. Both these factors produced catastrophic results, our records showing 100%

mortality. It can therefore be assumed that complete rest and free play for the rise in temperature are of paramount importance in the second stage of typhoid infection—the first being the incubation period—and that interference by such drugs as aspirin, quinine, and those of the sulphapyridine group, etc., for any length of time, is likely to affect the prognosis adversely if *Bact. typhosum* happens to be the responsible organism.

True relapses were recorded in 18 cases—over 6% of the total series. In 10 of these there was one relapse, in 7 others it was repeated, and one case relapsed three times. While a high percentage of positive blood cultures was obtained during the relapse period (in 14 out of 18 cases), on six occasions cultures were positive before the relapse had taken place. In four of these the temperature was on the down grade and two previous blood cultures had proved sterile; in the remaining two, cultures were sterile after the temperature had stayed subnormal for 4 and 5 days respectively. In all but two cases Vi agglutinins had practically disappeared during the subnormal stage of temperature. In these two exceptions, however, the curious combination of subnormal temperature, positive blood culture, and a Vi titre of 40–80 was encountered. The case with three relapses started well in that Vi agglutinins appeared early—on the ninth day—and continued until the 22nd day. Then there was a sudden drop, with temperature still at 100.2° F. Although the subnormal stage was reached on the 25th day, it remained so for only 5 days, the temperature then rising, with two similar subsequent events. These observations would justify the assertion already made as to the possibility of a relapse in the presence of unusual laboratory findings. The practice of a blood culture and an agglutination test when the temperature shows a downward tendency should therefore be considered worth a trial during the later stages of typhoid infection.

### Some Practical Points

Reference may now be made briefly to the application of observations discussed here from the prognostic and prophylactic points of view. In a case suspected clinically to be suffering from typhoid fever there is a tendency to assess the result of an agglutination test in terms of a positive or a negative Widal reaction, depending upon the titre of antibodies so detected. And, what is more important, a so-called negative Widal is taken to mean the exclusion of typhoid infection. From the present observations, and the experience of typhoid serology over a number of years, it cannot be too strongly emphasized that, in a case of remittent pyrexia, absence of Vi antibody or a lack of an appropriate rise in the titre of O agglutinins does not in any way exclude the possibility of the infection being typhoid in origin. It would therefore be better if the term "negative Widal" were entirely eliminated from typhoid terminology, since the meaning commonly attached to it leads to a sense of false security and indulgence in medication of a type likely to worsen the ultimate prognosis in the manner already pointed out.

The utility of Vi agglutination as a diagnostic measure has given rise to considerable differences of opinion. The present communication should throw some light on this problem. It will now be clear that an early rise in Vi agglutinins should be expected only in cases with mild symptomatology. Where complications have set in, a reasonably high Vi titre will be encountered only if and when the clinical tide turns in favour of the patient, and this Vi reading will persist at least for the next few days. In spite of observations to the contrary we have failed to discover this antibody as a natural agglutinin. Its presence had always been found to be associated with the existence of *Bact. typhosum* in the human body. Results to the contrary were mainly due to non-specific reactions likely to arise when suspensions of Vi I strain (Bhatnagar *et al.*, 1938), now employed almost universally for the purpose of Vi agglutination, had been preserved too long and the organism, either before or after the preparation of agglutinating suspensions, allowed to undergo S—R variation.

From the prophylactic point of view attention has already been drawn to favourable prognosis in an individual who has

had the benefit of multiple antityphoid inoculations over a number of years. Credit in such cases is usually given to the quality or type of vaccine employed. From a series of experiments on antibody production after T.A.B. inoculation in human beings it was pointed out a few years ago (Bhatnagar *et al.*, 1937) that protection against infection was best afforded by repetition at suitable intervals of stimuli given to the antibody-forming apparatus rather than by the quality or type of a single stimulus. The correctness of this view has now been confirmed by a change towards severity in the type of an average case of typhoid fever in military hospitals, due to a large influx of comparatively unprotected civilian personnel for military service and the drafts of non-tropical residents from over-seas, the majority of whom have had only one course of T.A.B. vaccine. It is the considered opinion that the practice of this prophylactic measure at shorter intervals during the first two years of military service in the Tropics—(a) on being called up, (b) on disembarking in a tropical country, and (c) subsequently at the end of 6 and 15 months—would result in a great improvement in the prognostic outlook in the event of actual typhoid infection.

### Summary

A close association between prognostic outlook and the results of laboratory investigations has been found to exist from the analysis of 280 cases of typhoid fever.

The cases have been classified into 6 groups, each with varying clinical and bacteriological characteristics.

Observations showed that if Vi antibody was present early in typhoid fever in a sufficiently high titre (50–250), and this titre was maintained over a number of days, the course of the infection would most likely be short (*simple type*).

In the *embolic type*—in which the Vi antibody was either absent or seldom above 10 to 20—improvement was preceded by a rise in Vi titre.

The *prolonged pyrexia (P.P.) type* resolved only when a sustained Vi titre was recorded. It must be stressed that, in the case of remittent fever, absence of Vi antibody or the lack of an appropriate rise in O agglutinins does not exclude the possibility of the affection being typhoid.

An abnormal rise in O agglutinins was observed in the *toxic type*, the titre varying from 2,000 to 20,000. Since a considerable fall in the O titre of serum always preceded recovery, the high rise of O agglutinins must be regarded as pathological.

In the *ambulatory type* complete rest and non-interference with the rise in temperature appear to be of the greatest importance in the second stage of the disease.

Relapses occurred in 6% of the whole series. Unusual laboratory findings appeared to be associated with the possibility of relapse.

An early rise in Vi agglutinins should be expected only in mild cases.

R. Torpin (*Amer. J. Obstet. Gynec.*, 1943, 46, 557), who records a personal case and has collected 27 others from the literature, states that spontaneous haematoma of the rectus abdominis muscle occurs in both white and negro women. Primary aetiological causes were trauma, cough, labour, strain, or, rarely, external injury. Other primary factors were, rarely, muscle degeneration from typhoid fever or influenza. Secondary aetiological influences were age, multiparity, and terminal stages of pregnancy. Conservative treatment consisted in early diagnosis, complete rest, and blood transfusion. The maternal mortality was 15% and the foetal much higher. Torpin's case was a negress aged 34, a 12-gravida; operation was performed without evacuation of the clot, and both mother and child lived.

## TREATMENT OF OCULAR INFECTIONS WITH PENICILLIN

BY

G. T. WILLOUGHBY CASHELL,  
M.B., B.S.Lond., F.R.C.S.Ed.

Squadron Leader, R.A.F.; Ophthalmic Specialist, R.A.F.

The use of penicillin in ophthalmology has led to the rapid and successful treatment of many acute bacterial infections, and the risk of intraocular infection following injuries has been lessened. The following report of a series of cases treated with this drug at an R.A.F. hospital is presented in substantiation of these remarks.

Before giving details of the cases it is necessary to outline briefly: (1) the principles of the treatment; (2) the types of ocular infection suitable for treatment; (3) the methods of application and dosage; (4) the assessment of the results.

### Principles of Treatment

Penicillin is admirably suited for surface application, and can be used in the form of drops in ophthalmic work. It is found that only small quantities need be employed: doses in the order of 1,000 units are sufficient to treat many cases. The drug has been used in the form of the calcium or sodium salt; both have been well tolerated in the eyes, and have been injected into the anterior chamber. It is known that penicillin is successful only when the primary infecting organism is sensitive to the drug in therapeutic concentration. It must also be capable of gaining access to the site of infection.

In the first place, organisms commonly found in ocular infections which are susceptible to the action of penicillin are *Staph. pyogenes*, the haemolytic streptococcus, the gonococcus, and the pneumococcus. Sensitivity to penicillin is not affected by a resistance to the action of sulphonamides. Sulphacetamide has been advocated for use in these infections. This drug has a negligible action against the staphylococcus, the commonest organism found in this series of ocular infections. Its action against the streptococcus is limited by pus, which contains antagonistic substances. On the other hand, penicillin in extremely low concentration completely inhibits the growth of both staphylococci and streptococci, and its action is in no way impaired by pus. Experiments during this survey also show that the organisms isolated from ocular infections—the bacillus of Petit and the Morax-Axenfeld bacillus—are insensitive to penicillin when tested *in vitro*.

In the second place, the eyelids, conjunctival sacs, corneae, and lacrimal sacs are ideal for the use of penicillin, as it can be applied with ease, and at the same time gains access to all parts of the ocular and palpebral conjunctivae, the lid margins, and the lacrimal sacs.

### Types of Ocular Infection Suitable for Treatment

(a) Acute conjunctivitis and blepharitis, which react well to penicillin; the infections that are usually found to be due to *Staph. aureus*, streptococcus, or pneumococcus, and are often associated with marginal keratitis and corneal ulceration. (b) Chronic blepharitis, usually due to *Staph. aureus*. (c) Infected corneal ulcers, either due to trauma or associated with the above conditions. (d) Perforating corneal injuries with prolapse of the iris and the risk of intraocular infection.

### Methods of Application and Dosage

Penicillin can be used in the eye in the form either of drops or of ointment. Irrigation of the anterior chamber can be carried out with a solution of the drug in certain cases in which infection of that structure has taken place through a perforating wound. A dosage of penicillin drops, strength 500 (Oxford) units per c.cm., is efficacious. Penicillin is also of value as an ointment made up in a soft lanette wax base of 500 units per gramme. In acute cases, and in perforating wounds where infection is apparent within 24 hours of the injury, applications of penicillin should be made at half-hourly intervals for the first 24 hours. Thereafter the applications

can be reduced to two-hourly and, later, four-hourly. From the cases quoted below it will be seen how rapidly ocular infections are rendered sterile. It is possible to save eyes which would otherwise undoubtedly have been lost from intraocular infection.

It must be remembered that penicillin loses its potency after keeping. It is necessary to store it carefully in a refrigerator, and it is advisable to have small quantities made up at a time. The solution should be freshly prepared every 14 days.

### Assessment of Results

Control of the cases was done by clinical assessment of recovery and by cultures taken from the infected area. It was found essential to keep a close watch on the infection, and directly a case was seen cultures were taken from the lid margins, conjunctival sacs, or corneal surfaces, depending on the site of the infection. Ideally these cultures should be taken every 48 hours. They generally become sterile within 7 days.

### Cases of Blepharitis

Case	Type of Discharge and Duration	Culture	Penicillin per Day (in Oxford Units)	Sterile in Days	Result
1	Watery; 12 mths.	Staph. pyo.	58	12	Lids clean
2	Crusting	" "	130	13	Healed
3	Watery; 2 yrs.	" "	40	10	Lids clean
4	Crusting; 2 mths.	" "	40	12	Satis.
	Relapse 2 mths. later	" "	40	14	Improved
5	Watery; 14 yrs.	Sterile	390	20	"
6	Dry, 7 mths.	Staph. albus	1,800	10	Clear
7	Dry	" "	1,560	10	"
8	Serous; 5 yrs.	" pyo.	1,560	13	Clear
9	Dry; 3 yrs.	" "	420	13	"
10	Scaly; 5 days	" "	420	8	Clear
	(4 days treated with mercurochrome and argyrol—still Staph. pyo.)				
11	? 1 yr.	Staph. pyo.	58	14	Clear
12	Scaly; 3-4 yrs.	Sterile	174	7	Clear
13	Watery since childhood	" "	390	12	"
14	Watery; 6 mths.	Staph. pyo.	420	14	"
15	" 5 mths.	" albus	390	6	"
16	" 2 yrs.	" pyo.	420	12	Sterile
17	Scaly; 1 yr.	" "	420	6	Clear
18	Scaly since infancy	" "	420	4	"
19	"	" "	420	12	Sterile
20	Scaly since childhood	" "	420	10	"

In the cases of blepharitis the history varied from 5 days to 15 years; all had a typical watery discharge, with crusting of the lashes and redness and soreness of the lid margins. The cultures showed *Staph. pyogenes* in 15 cases and *Staph. albus* in 3 cases; no definite organisms were isolated from the remainder. The average number of units of penicillin used in each case per day was 560, given either twice or three times a day as drops made up in 500 units per c.cm. The average period to elapse before obtaining a sterile culture was 12 days, and at the end of that time discharge had ceased and the lids were clean and comfortable.

A relapse of the blepharitis occurred in 2 cases—Nos. 4 and 19. In Case 5 after 20 days' treatment the condition had only improved slightly; and here the history was that the infection had been present for 14 years. It is difficult to be dogmatic about the permanency of the results of treatment in these chronic cases without a very careful follow-up, but there is no doubt that in most of the cases the lid condition improved very markedly under treatment.

### Cases of Acute Conjunctivitis

Case	Type of Discharge and Duration	Culture	Penicillin per Day (in Oxford Units)	Sterile in Days	Result
1	Watery; 3 mths.	Staph. pyo.	390	11	Clear
2	"	" "	195	7	Eye white
3	Purulent; 11 days	Diphtheroids	40	11	"
4	Watery; 7 days	Staph. pyo.	130	12	"
5	" since 1918	Diphtheroid; streptothrix	390	21	Improved
6	" 5 days	Staph. pyo.	390	21	Clear
7	" 3 mths.	" "	130	7	Eye white
8	" 6 yrs.	" "	130	14	Sterile
9	" 7 days	" "	390	6	"
10	Purulent; 3 days	" "	390	4	"

The history of the cases of acute conjunctivitis varied from 7 days to frequent acute relapses over a period of years.

*Staph. pyogenes* was present in 8 cases. The average number of units each case received per day was 190, and sterile cultures were obtained in 10 days; the eyes were white.

In this series there was no doubt about the dramatic improvement in the condition of the eyes under treatment. One case in particular—No. 9—may be cited. This man came in with a very severe infection of both eyes, superficial keratitis, extreme photophobia, and blepharospasm, and the weeping eyes caused a spreading infection of the skin of the lids, which eventually affected the whole of the face and down the neck. After 48 hours' treatment with penicillin the eyes could be opened without discomfort, the conjunctiva had become almost white, and the skin of the lids was clearing rapidly. Within a week the whole condition had subsided.

#### Cases of Corneal Ulcer

Case	Type of Discharge and Duration	Culture	Penicillin per Day (in Oxford Units)	Sterile in Days	Result
1	Watery; 7 days	B. of Petit	195	4	Healed
2	" 13 "	<i>Staph. pyo.</i>	195	8	"
3	" 3 "	" "	195	10	"
4	" 4 mths.	" <i>albus</i>	195	12	"
5	" 1 mth.	" <i>pyo.</i>	195	8	"
6	" 3 days	" "	40	9	"
7	Purulent; 4 mths.	" "	130	18	"
8	Watery; 7 days	" "	195	4	"
9	" 5 wks.	" "	195	12	"
10	Purulent; 2 days	" "	195	5	Sterile

The history varied from 3 days to 4 months. There were 8 cases of *Staph. pyogenes*, 1 of *Staph. albus*, and 1 of the bacillus of Petit. Cases were given 160 units per day, and were healed in 9 days. Ulceration of the cornea healed rapidly in most cases, and the associated conjunctival condition became clear within 48 hours of starting treatment. The case which grew the bacillus of Petit responded to treatment, although it has already been proved that the organism is insensitive to penicillin.

#### Cases of Perforating Injury

Case	Type of Discharge and Duration	Culture	Penicillin per Day (in Oxford Units)	Sterile in Days	Result
1	Purulent; perforation 3 days	<i>Staph. pyo.</i>	360	9	Panoph (6 days later excision)
2	Purulent perforation 6 hours	" "	600	4	Clean (cyclitis; excision)
3	Purulent; perforation 5 days	<i>Staph. pyo.</i> ; diphtheroids	360	16	Clean (cyclitis; excision)
4	Perforation 12 hrs.; hypopyon	<i>Staph. albus</i>	130	17	Clean
5	Operation for cataracts; inspection 24 hours	Diphtheroids	360 (Irrigated AC)	33	Clear
6	Perforating injury; hypopyon	<i>Staph. pyo.</i>	600	4	Sterile
7	Burn of conjunctiva	" "	360	4	Clean
8	Sulphuric acid burns	<i>Str. haem.</i>	360	4	Sterile
9	Perforating injury	<i>Staph. pyo.</i>	360	6	"
10	Injury to R.E.; loss of eye with infected socket	" "	130	4	"
11	Superficial corneal abrasions	" "	130	2	Clean
12	Orbital wound	" "	130	3	"
13	Infected stitches; dacryocystorhinostomy	" "	130	3	"
14	Rupture of cornea	" "	100	4	"

In each case there was considerable infection of the cornea, with acute conjunctivitis; but, with penicillin, panophthalmitis was avoided in 5 cases out of 6. The organisms again were *Staph. pyogenes* in the majority of cases, and the conjunctival sac in each instance was made sterile in an average of 10 days. However, 3 cases required excision later owing to a chronic cyclitis.

There is no doubt that infected wounds which involve the eye, the orbit, or the lids react well to penicillin. Of these cases of perforating injury Case 1 was not available for treatment until 3 days after the injury, and intraocular infection had already started. Cases 2 and 3 had definite infections of the anterior chamber, which cleared up with penicillin,

although chronic cyclitis supervened. Cases 4, 5, and 6 all had hypopyon, which also disappeared under penicillin treatment. Case 8 was interesting, as to prevent symblepharon in the lower fornix a contact lens was made, and before this was fitted an acute streptococcal infection of the conjunctiva was completely controlled within 4 days. Irrigation of the anterior chamber was carried out in Cases 5 and 6, and these eyes would undoubtedly have been lost from panophthalmitis.

#### Cases of Dacryocystitis

Case	Type of Discharge and Duration	Culture	Penicillin per Day (in Oxford Units)	Sterile in Days	Result
1	Purulent; 3 years	Pneumococci; diphtheroids	420	9	Clean
2	Muco-purulent	Diphtheroids	420	7	"
3	Purulent	Pneumococci	420	5	Sterile

The 3 cases of dacryocystitis responded rapidly to treatment, and a sterile, clean lacrimal sac was noted within 5 to 9 days in each case. The infection was pneumococcal in 2 of the cases, and dacryocystorhinostomy was successfully performed in each instance, with clean healing wounds.

#### Treatment

It has been suggested that with a standard solution of 500 units per c.cm. the following dosage is adequate in the types of infection indicated:

**Blepharitis.**—One drop in each eye three times a day.

**Acute Conjunctivitis.**—One drop in the affected eye 4-hourly during the acute stage; later, three times a day.

**Corneal Ulceration.**—One drop in the ulcerated eye 4-hourly until clean; later, three times a day.

**Perforating Injuries.**—One drop in the injured eye half-hourly during the first 24 hours, and, if possible, instillation into the anterior chamber.

Treatment should be continued for 7 days after the first negative swab, or after clinical evidence of cure, in order to prevent relapse.

#### Summary and Conclusions

An attempt has been made to indicate the type of ophthalmic case that is suitable for treatment with penicillin and the dosage of the drug required. The following points arise from the investigation:

1. Penicillin holds a very important place in the treatment of ocular infections.

2. Compared with the dosages required in other branches of medicine and surgery, the amount necessary for the adequate treatment of all acute ocular infections in an ophthalmic unit is small.

3. It is effective against *Staph. aureus*, the haemolytic streptococcus, the pneumococcus, and the gonococcus.

4. It can be used in the form of drops or ointment, the best strength being 500 units per c.cm. Frequent applications are required in the initial stages of treatment. Experience has shown that treatment with drops is efficacious, and, on the whole, the drug is easier to apply by this means.

My best thanks are due to Group Capt. W. E. Barnes for his help and encouragement; to Prof. Florey and the Medical Research Council for the supplies of penicillin; and to Flight Lieut. Bodenham for his assistance in the treatment and his advice as to dosage.

Salaries of £65 a year rising by annual increments of £5 to £95 for assistant nurses and of £35 to £40 a year for probationers in non-training hospitals are recommended in the third report of the Taylor Committee on salaries of nurses in Scotland. Part I deals with salaries of those nurses not covered in the two earlier reports, including nurses on the new State list who receive the same as State-registered nurses; nurses above the grade of charge nurse in mental hospitals, who will have scales generally comparable with those in general hospitals; nurses in public assistance institutions and convalescent homes; cottage nurses; and orthopaedic nurses. Part II fills in certain gaps and amplifies or modifies scales for nurses in general, fever, children's, and maternity hospitals, in the domiciliary midwifery service, the public health service, and the district nursing service. Part III clears up some doubtful points of the earlier reports. The only matters now outstanding are superannuation, and salaries and conditions for nurses, up to the grade of charge nurse, in mental hospitals.

# CONTROL OF VERY SEVERE DIABETES BY A NEW ARRANGEMENT OF INSULINS

BY

R. D. LAWRENCE, M.D., F.R.C.P.

AND

WILFRID OAKLEY, M.D., F.R.C.P.

(The Diabetic Department, King's College Hospital)

Some cases of diabetes are so severe and so very difficult to control that it may be useful to describe a new method of treatment which we have found successful in many such cases in the past few years. We do not use "control" in the purist's sense of keeping the blood sugar normal and the urine sugar-free throughout the 24 hours, but merely of preventing the phases of intense glycosuria and ketonuria which occur daily when this type of case is treated along conventional lines. It is true that these phases are usually quite short, but, in the event of complications such as acute infection or gastrointestinal disturbance with vomiting, they may act as the starting-point of a more prolonged and serious relapse; this is particularly true of pregnant diabetics, in whom the tendency to ketosis is so often accentuated by a lowered renal threshold. It is also possible that these phases may, if sufficiently prolonged, be responsible for failure of growth and development in some children, whose instability is such as to make control by ordinary methods impossible.

Undoubtedly the best and most economical way of treating these very severe diabetes is with multiple injections of soluble insulin at four- or six-hourly intervals; but this is not practicable except over short periods of emergency, and we aim at the routine use of not more than two daily injections. The depot insulins, particularly P.Z.I., have made this possible in most, but not the exceptionally severe, cases. These require such high concentrations of insulin that protamine insulin with its slow absorption is almost useless, as it never liberates enough circulating insulin to be effective. In treating these very severe diabetes, therefore, we rely on soluble insulin to control the hyperglycaemia resulting from ingested carbohydrate, and use P.Z.I. to prevent, if possible, relapse due to endogenous sugar formation, particularly by night. In practice we arrange the insulin therapy for our severe cases in one of the following ways:

## Mixed Dose of Soluble Insulin and P.Z.I. in the Morning before Breakfast

This is the most convenient method, but is suitable chiefly for those moderately severe cases which neither require large doses of insulin nor relapse seriously when the soluble insulin has ceased to act and the patient depends on P.Z.I. alone—namely, in the late afternoon, night, and early morning. Heavy glycosuria is common after the evening meal on this regime, but is usually of short duration and of no clinical importance. The insulins are given together in the same syringe and the correct proportions worked out for each case, the dose of soluble insulin being usually larger than that of P.Z.I. to allow for the precipitation of some of the former by the excess protamine present in the latter. In very severe cases, however, this method may completely fail to control the diabetes, hyperglycaemia being persistently present, with heavy

FIG. 1.—Very severe case (temporary or permanent).

glycosuria and ketosis in the morning and possibly also at night. The P.Z.I. appears only to detract from the action of the soluble insulin without exerting much effective action of its own (see Fig. 1).

## Mixed Dose of Soluble Insulin and P.Z.I. before Breakfast and Soluble Insulin before Dinner or Supper

This arrangement probably gives the best control possible by two injections in the majority of severe cases. The addition of a small injection of soluble insulin towards the end of the day prevents the evening relapse, and we think is best given, if possible, at about 5 or 6 p.m., so that its action may be nearly over before bedtime. This timing of injections is particularly suitable for children and others who combine their tea and evening meal. While this method is an undoubted improvement on the first for very severe cases, it may fail for the same reasons. The evening soluble insulin may prevent heavy nocturnal glycosuria and frequency, but does not act long enough to prevent a relapse by the morning, after which hyperglycaemia again tends to persist throughout the day (see Fig. 2). One advantage of this method is that the need

FIG. 2.

for an evening dose may be only temporary and it can be stopped later without an entire rearrangement of the treatment.

## Morning and Evening Injections of Soluble Insulin

In spite of the many advantages of depot insulin this method remains a most satisfactory one in many severe diabetes. Its advantages are simplicity and adaptability, which make it particularly suitable for those whose activities and meals are apt to be irregular. Again, however, in very severe cases, and especially those who are highly insulin-sensitive, this method is liable to fail on account of its tendency to produce a swinging blood sugar and, unless large buffer meals are included in the diet, severe hypoglycaemic reactions alternating with periods of intense hyperglycaemia and ketosis. This tendency constitutes a particular problem at night, when the danger of nocturnal hypoglycaemia can only be avoided at the cost of a very high fasting blood sugar, often accompanied by heavy ketosis in the morning (Fig. 3). It was in an endeavour

FIG. 3

to overcome this serious drawback to the use of two injections of soluble insulin in severe diabetes that we decided to try a new arrangement of soluble insulin and P.Z.I.

## Morning Soluble and Evening Mixed Soluble and P.Z.I.

This method has certain advantages, both in theory and in practical effects, over those already described. The use of soluble insulin alone in the morning gives a strong rapid insulin action at a time when it is chiefly needed, whereas when given with P.Z.I. a certain proportion of the soluble insulin is converted into protamine insulin, necessitating a considerably larger dose of soluble to produce the same prompt effect. If this is remembered, together with the fact that P.Z.I. may be almost without effective action in some severe cases, it will be seen that enormous mixed doses may be given in the morning to such cases with no greater benefit

than may result from a comparatively small dose of soluble insulin given alone. We have demonstrated the truth of this observation in a number of our cases by withdrawing suddenly from the morning mixed dose all the P.Z.I., amounting to 30 or 40 units or more, the only result being a lowering of the noon blood sugar. Such cases are exceptional, but their existence should be remembered whenever very large doses of P.Z.I. appear to be having little or no action.

The use of a mixed dose at night might in theory be expected to prevent a high fasting blood sugar and morning ketosis, and also possibly to exert some mild hypoglycaemic action on the following day, especially before meals. The only real danger would appear to be the possibility of nocturnal hypoglycaemia, and, to avoid this, the dose of P.Z.I. should be kept relatively low and always less than that of the soluble insulin given with it.

Experience of this method of treatment in some 100 cases of the very severe type, all of which had high fasting blood sugars and morning ketosis on other regimes, has confirmed, in our opinion, the theoretical advantages put forward, and convinced us that the addition of a small dose of P.Z.I. to the evening injection of soluble insulin does in fact result in the lowering of the fasting blood sugar, with consequent decrease in morning insulin requirement, and disappearance of ketone bodies from the early morning specimen of urine (Fig. 4). Treatment along these lines has been particularly

FIG. 4

successful in pregnant diabetics, several of whom have asked to continue on an evening mixed dose after delivery.

We have also had good results in a number of children, but, although we have seen little or no nocturnal hypoglycaemia in any of the cases so treated, we feel that particular care should be taken to avoid this in children by using the smallest effective evening dose of P.Z.I. and always giving an adequate bedtime feed. We have tried similar small doses of P.Z.I. with the morning soluble insulin to try to prevent relapse in the late afternoon, but with less success.

## Medical Memoranda

### Traumatic Perforation of the Appendix

Perforation of the appendix is common enough in itself, but when due solely to trauma is very unusual. Such a case was seen recently, and is considered worth recording.

#### CASE HISTORY

A Canadian soldier aged 20 was admitted to hospital at 11 a.m. on Nov. 9, 1942, with the following history: At 8 a.m. he had been crushed between a wall and a slowly moving lorry; his abdomen, more particularly the upper part, bearing the brunt of the injury. He did not lose consciousness, but complained immediately of abdominal pain, mainly epigastric.

On examination the patient was seen to be a well-developed, robust young man. His colour was good, but he complained of abdominal pain, especially in the upper abdomen. There was neither nausea nor vomiting; no food had been taken since the accident, nor had morphine been administered. His temperature was 98°, pulse 80, and respirations 20. The abdomen showed no signs of contusion or any abrasions and moved fairly well on respiration. There was diffuse tenderness, but of only moderate degree and most

An equally diffuse, but slight, degree of rigidity, but no true rigidity. Release to a slight degree over the whole abdomen. There was no evidence of free fluid in the peritoneum, liver dullness was unimpaired, while peristaltic sounds were excep-

tionally prominent; no shoulder-tip pain was felt. Rectal examination revealed nothing; neither did clinical examination of the chest. There was no bony tenderness or any other sign of a fracture. A provisional diagnosis of contused abdominal wall was made and a conservative attitude adopted.

One hour later the pulse was 60 and of very good volume, but otherwise the patient's condition was unchanged. During the afternoon the pulse rose gradually until it reached 80 by 5 p.m. He was also complaining of hypogastric pain, apparently due to a full bladder, no urine having been voided since the accident. A catheter was passed easily, and a specimen of normal urine was obtained, showing there was no lesion of the urinary tract. Still no change was observed in the abdominal signs, but the rising pulse—the volume not quite so good as at first—was causing some anxiety, so it was decided to explore the abdomen unless the clinical condition showed a marked improvement in the next hour or so. No improvement occurred, and at 7 p.m. the temperature rose suddenly to 101°.

At 8 p.m. a laparotomy was begun under gas-oxygen-ether anaesthesia. A right paramedian incision was employed; no blood or intestinal contents could be seen in the peritoneal cavity. On the small intestine were numerous abrasions where the serous covering had been injured, but there were no perforations or any evidence of loss of vitality. A tear 3 in. long was found in the mesentery at the ileo-caecal junction. It was at right angles to the gut, but produced no visible effect on it; one fairly large artery had been torn across, without haemorrhage at the time of injury, though some occurred while manipulating the bowel. The artery was tied and the rent in the mesentery sutured. At this stage a detached appendix epiploica and a small piece of faecal matter were found in the pelvis. Examination revealed that the perforation of the large bowel was confined to the tip of the appendix, while the appendix epiploica appeared to be from the pelvic colon.

The appendix itself was about 5 in. long, very mobile—being actually discovered just above the pelvic brim—and devoid of any sign of inflammation. At the tip was an irregular perforation about 1/3 in. in length. Treatment presented no problems and the appendix was removed in the usual way. The abdomen was closed and a rubber dam drain left in the peritoneum for 48 hours.

Intravenous saline was started, 1/4 gr. of morphine was given 6-hourly, and a Ryle tube was placed in the stomach and aspirated every hour. Soluble sulphapyridine was given intravenously—2 g. followed by 1 g. 4-hourly for 72 hours.

During the first few days after the operation the abdomen was distended and very silent, suggesting that there was some peritoneal inflammation, which was not unexpected. Thereafter a mass developed in the pelvis, but this resolved without surgical intervention, and the patient made slow but steady progress, being discharged to a convalescent home 6 weeks after the operation.

### DISCUSSION

Since the days when acute appendicitis became common the position of trauma as an aetiological factor has constantly been under review. It was first thought that trauma never caused acute appendicitis, but it is gradually being accepted that it may occasionally bring on an attack. As Maes and McFeiridge (1935) wrote, the exact mechanism of traumatic appendicitis has never been satisfactorily established. There is no previous case on record of rupture or even bruising of the appendix. It had also never been scientifically proved, operation usually not being early enough to detect evidence of trauma before obliteration by inflammation. Ludington in 1923 described acute appendicitis in a girl aged 10, with rupture of all anatomical coats in an appendix distal to an adhesion, 30 hours after a fall. McCarthy and Magrath in 1938 reported two cases in which the appendix and mesentery were torn away from the caecum.

The case recorded above may shed some light on the controversy, as the appendix was free from previous disease and uninfamed, and the rupture was obviously due to trauma. This injury, or one in which the coats are damaged and not ruptured, could produce a spreading inflammation of the appendix. The case also proves conclusively that the appendix can be injured without serious damage to any other viscus.

I wish to thank Col. J. M. Elliott, Army Medical Services, for permission to publish this case.

R. A. Palmer and H. S. Mitchell (*Canad. med. Ass. J.*, 1943, 49, 465) record two cases of march haemoglobinuria in soldiers aged 19 and 21. Its pathogenesis is still unknown, but they suggest that the paroxysms are not due to increased haemolysis but to some unknown abnormality present during erect exertion interfering with the clearing from the plasma of the haemoglobin liberated in the normal destruction of senile erythrocytes.

## Reviews

### ENDOCRINOLOGY OF CHILDHOOD

*Endocrine Disorders in Childhood and Adolescence.* By H. S. Le Marquand, M.D., M.R.C.P., and F. H. W. Tozer, M.D., M.R.C.P. (Pp. 298; illustrated. 15s.) London: Hodder and Stoughton. 1943.

How recent is the interest taken in the endocrinology of childhood is shown by the fact that neither the word "pituitary" nor "endocrine" appears in the index of the 1924 edition of a well-known textbook of children's diseases. Yet the endocrine system asserts itself before birth and is actively concerned with growth—the conspicuous feature of early life. We welcome, therefore, this book on *Endocrine Disorders in Childhood and Adolescence*, by Dr. H. S. Le Marquand and Dr. F. H. W. Tozer, as a valuable contribution to the subject. They have assimilated the literature and tested the conclusions thereof in the light of their own clinical observations. Like most recent observers, they are increasingly struck by the predominant role of the pituitary and its close association with the hypothalamic centres. Yet they find that pituitary disorders, though relatively common, are often unrecognized. Valuable evidence may be obtained by seeing other members of the family, and they are impressed with the frequency with which "problem children" present minor stigmata of endocrine imbalance. The complexity of conditions arising can only be attributed to a dissociation of pituitary functions, and in the chapter on the physiology of the endocrine system the vexed question is discussed whether each of these manifold functions has its own specific hormone, or whether (as Collip believes) there are not more than three hormones, modified as required by the needs of the body. That these tiny glands containing only three types of cells should elaborate at least eleven specific substances, some of which, such as the lactogenic, may never function throughout life, seems highly improbable. The work of the organic chemist showing what profound changes in action may result from slight changes in chemical constitution certainly adds point to Collip's view. The close interrelation between all the endocrine glands is insisted on, which is particularly obvious in the case of the pituitary and the gonads. The descriptions of the various clinical syndromes are lucid, and the discussions of them maintain a nice balance between dogmatism and scepticism. A number of photographs illustrate some of the cases under the care of the authors, and a useful table of the commercial preparations of sex hormones is appended.

Although the psychological basis of anorexia nervosa as distinct from organic defects in the anterior pituitary is realized, the advocacy of energetic endocrine treatment, if evidence of hypogonadism be found, may tempt some practitioners to carry out to the neglect of the more troublesome and delicate essential psychological factor. This is the only criticism we have to make of an admirable account of endocrine disorders in early life and one which imparts much information in a reasonable compass.

### X-RAY DIAGNOSIS

*Outline of Roentgen Diagnosis.* By Leo G. Rigler, B.S., M.D. Second edition (Pp. 196; illustrated. 40s.) London: J. B. Lippincott Company. 1943.

The second edition of Leo G. Rigler's *Outline of Roentgen Diagnosis* is, like the first, based on lecture notes prepared by him for undergraduate teaching. These notes, revised, expanded, and now published in book form, are designed, according to the preface, "as a supplement to diagnostic lectures to undergraduates, as a text in teaching extension courses to general practitioners, as a study outline for graduate students, and, by radiologists, as a synopsis for lectures." It is, in effect, a synopsis of x-ray diagnosis, and exhibits both the virtues (if there be virtues) and the faults of such works. The text occupies 196 pages; the illustrations—227 in all—are grouped in a series of plates at the end. In conformity with the object of the book, radiographic technique has been omitted.

The text is well arranged, but tends too much to be a catalogue of x-ray signs, and fails, like most synopses, to assess the value of the sign, or to indicate its significance in relation

to the pathological process or disturbance of function. There are a number of errors and omissions in the text—for example, the statement that in the female the fifth lumbar vertebra rises high above the crest of the *sacrum*; even correcting the *lapsus calami* this is not true. Again, the author states that "the [x-ray] diagnosis of either acute or chronic mastoiditis can be made with great certainty, especially if it is one-sided"—an enthusiastic claim, to say the least of it. In discussing the position of a Colles's fracture no mention is made of the inclination of the radial articular surface in the lateral view, and in describing the signs of acute maxillary sinusitis the fluid level is omitted. In atelectasis of the lower lobe of the lung the retrocardiac triangular shadow is not mentioned, nor is any account given of the signs of atelectasis in the other lobes. An unhappy word, "radiability," is used throughout the book when describing the translucency of a structure to x rays. If it means anything the word would indicate the capacity of the structure to radiate.

The half-tone illustrations of radiographs are of good quality and well chosen to illustrate the commoner conditions. The line diagrams are excellent. Mention should be made of a novel feature in the illustrations of bone lesions drawn by Miss Hersch. These are very successful in combining in one drawing the salient features of the lesions illustrated.

While this book is too compressed to be of much value to the real student of radiodiagnosis it may commend itself to those undergraduates who require a concise outline of a large subject. Of itself it may fail to give them the most essential feature—a real perspective of the subject.

### APPLIED CHEMISTRY

*Thorpe's Dictionary of Applied Chemistry.* By the late Jocelyn Field Thorpe, D.Sc., F.R.S., and M. A. Whiteley, D.Sc. Fourth edition, revised and enlarged. Vol. VI; with an Index to Vols. I to VI by Dr. J. N. Goldsmith. (Pp. 611. 80s.) London: Longmans, Green and Co. 1943.

A full appraisal of *Thorpe's Dictionary of Applied Chemistry* would call for its review in many different aspects. Under the title of 'helium, for example, there is found first a detailed history, with an account of its geographical distribution; next there is what amounts to a treatise on low-temperature physics with data relating to the remarkable properties and behaviour manifested in the neighbourhood of absolute zero; and in a calendar of general information we are given an account of the uses of helium—among which is its increasing medical application. In certain types of respiratory obstruction it is found that a mixture of helium and oxygen is easier to breathe than the corresponding nitrogen mixture and diminishes muscular effort. The same mixture is advantageous as a supply to divers, reducing the liability to "divers' bends." This monograph on helium is descriptive of the pattern of all. The range of subjects covered by Thorpe's dictionary is extensive and includes a great diversity of kind. An instance of this diversity is shown by the appearance of a monograph describing the practice of dyeing human hair and explaining the chemical nature and action of the dyes used for the purpose. There are monographs on the ideal or perfect gas, on interatomic distances, and on high-pressure reactions. The diversity of subjects is matched by the diversity of authorship of the monographs. As the sources of authoritative knowledge the names of more than sixty well-known scientists appear in the list of contributors to the pages of this volume.

The dictionary is a credit to the contributors, to the editors and others engaged in its production, and is worthy of the place it fills in English chemical literature.

### Notes on Books

*The Handbook of Tropical Medicine*, by Drs. ALFRED C. REEL and J. C. GEIGER (Oxford University Press; 9s. 6d.) is small enough to be carried conveniently in the pocket. It differs from the usual run of books on tropical medicine in that it confines itself almost entirely to the clinical features of tropical diseases, their diagnosis, treatment, and prevention. There are no lengthy descriptions of the life-histories of the parasites concerned, nor are there any illustrations. The little book is essentially one for the clinician who is given all essential information for the handling and treatment of his cases. It is well written and remarkably free from inaccuracies, and it deals with all the important tropical diseases

which it is unnecessary to enumerate here. Anyone going to the Tropics or having to handle patients from the Tropics cannot do better than arm himself with this admirable little book.

Two articles from the *Approved Schools Gazette* have been reprinted in pamphlet form: one is entitled "Nocturnal Enuresis in Institutions for Children," by Dr. A. H. Norris, ex-chief inspector, Children's Branch, Home Office; and the other is a short addendum by Dr. A. E. Carver, psychiatrist-in-charge, Nuneaton Child Guidance Clinic. Dr. Norris suggests that any medical man applying to the Chief Inspector, Children's Branch, Home Office, Whitehall, S.W., would be sent a copy. His object in writing the article was to give workers in residential schools some guidance for helping the child on sound and safe lines. The advice is based on long experience of children in hospitals or sanatoria, while working as the medical officer of an education committee, and particularly through visits paid to several hundred residential schools and homes for children.

The Child Welfare Department of University College Hospital, London, has prepared a leaflet, *The Care of Your New Baby*, for mothers to take home with them when they leave hospital with their babies. It is not intended as a substitute for regular attendance at the local child welfare centre. Copies (price 2d.) can be obtained from the Secretary, University College Hospital, Gower Street, W.C.1, or from H. K. Lewis and Co., 136, Gower Street.

## Preparations and Appliances

### INTRAVENOUS ANAESTHESIA BY GRAVITY-FEED APPARATUS

Dr. J. L. GRIFFIN, honorary anaesthetist, Taunton Hospital, writes:

When intravenous anaesthesia was first introduced it was hailed as the coming anaesthetic, but since the technique of administration was imperfect, fatalities occurred, and it came to be considered dangerous for any but short operations in the healthy young adult. This was largely due to two causes: (1) administration by the inexperienced with frequently no means of resuscitation at hand; (2) the thoroughly bad practice of giving a large pre-judged dose of the drug rapidly in order to obtain deep anaesthesia for a short period.

Intravenous anaesthesia is now becoming more widely used every day for major as well as minor surgery, including cases previously thought unsuitable. Its chief advantages are: *To the Surgeon*—(1) quiet respiration, (2) efficient relaxation, (3) less haemorrhage; *To the Anaesthetist*—(1) rapid induction, (2) absence of second-stage complications, (3) a relaxed jaw and fewer difficulties with the air-way in consequence, (4) a slow, steady pulse rate with only a slight fall in blood pressure; *To the Patient*—(1) no mask over the face, (2) a rapid black-out, (3) post-operative vomiting rare, (4) an awakening as from natural sleep. If it can be given in carefully graduated doses throughout the operation—supplemented if required with gas-and-oxygen—it approaches the ideal.

Below is a description and illustration of an apparatus for its continuous administration, with saline (in use at Taunton Hospital), which I hope will be of interest to anaesthetists.

#### The Apparatus

It may be conveniently described in two parts: (1) A metal upright tube which is fastened to the left rear leg of the table Boyle's or other anaesthetic trolley. This carries a fibre panel which is adjustable to height and distance from the upright, enabling it to be placed over either the table or the patient's arm. The panel supports spring holders for the funnels and large fine-adjustment screw-clips (Baird and Tatlock). It has also a three-legged stand for use where there is no convenient table. (2) The sterilizable part of the apparatus, which consists of two graduated glass funnels (Allen and Hanburys) with bakelite covers, one to hold 300 c.cm. saline and the other 40 c.cm. of the anaesthetic solution. The rubber tubes leading from these funnels pass through the screw-clips and are joined by a glass U-tube to a single drip the lower end of which is tapered to take the fine-bore tubing (2 mm.) which leads in turn to a fine glass indicator and intravenous needle.

#### Technique

The patient, if an adult, receives 2 oz. glucose in water three hours before operation, 1/3 gr. omnopon plus 1/150 gr. scopolamine one hour before. This reduces any toxic effect and also the total dose required—e.g., an operation, fascial repair of obturator hernia, lasting 24 hours, required only 1½ g. pentothal.

The glass and tubing parts, having been assembled and sterilized in a small partitioned bag, are attached to the panel. A sterile towel is placed on the table with the usual equipment for preparing the

anaesthetic solution (usually 40 c.cm. of a 2½% solution of pentothal with 3 c.cm. of coramine). The funnels having been filled, the screw-clip on the saline tube is turned on to expel the air and fill the fine-bore tubing, and then turned off. The clip on the anaesthetic tube is then turned on and off to ensure its subsequent smooth working.

The patient's right arm is secured to a splint and an aneroid type sphygmomanometer used, first to check blood pressure, then to make the veins prominent. This is preferable to a bandage or tubing, as correct pressure can be maintained until the needle is shown by the glass indicator to be in the vein.

The saline is started, the arm pressure released, and the needle strapped by adhesive tape to the arm. The anaesthetic solution is given in doses as follows:

The saline is turned off, the anaesthetic turned on, and the drip and graduations watched until the required amount has been given. The anaesthetic is then turned off and the saline recommenced. This avoids any backwash or tendency to levelling of the fluids in the funnels if both were turned on together.

#### Advantages of the Apparatus

1. It forms a single stable unit with the Boyle's, and is in no one's way.
2. It obviates the need for an assistant to hold the jaw and leaves the anaesthetist free to give gas-and-oxygen and the necessary doses of the intravenous anaesthetic simultaneously.
3. Because of the fine-bore tubing and tapered drip the dead space is reduced to 3 c.cm. and the effect of each dose is obtained in about 50 seconds, giving minute-to-minute controllability.
4. The administration of saline and coramine intravenously minimizes the slight fall in blood pressure. Plasma may be given later through the same needle (No. 1 hypodermic, short bevel).
5. There is no loss of time between cases, or waste of anaesthetic, as the apparatus may be used throughout an operating session; all that is necessary is to change the fine tubing, indicator, and needle between cases. Sets of these may be ready sterilized.
6. With such a gravity-fed apparatus there is no risk of air or oxygen embolism as there may be with a pressure-fed apparatus.

I am greatly indebted to Mr. Hassan (motor engineer), who kindly constructed the metal parts, and to M. Muers, Ph.D., who designed the glass and tubing.

## BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 25 1944

## THE WHITE PAPER DEBATE

The scanty attendance in the House of Commons during the debate on the White Paper last week was, we believe, a measure of the general lack of interest in the country as a whole in a matter which concerns it profoundly. The facts that Left-wing speakers commended the White Paper and determined to resist any attempt to whittle it down, and that Conservative speakers offered to support doctors in their opposition to some of the proposals in the Paper, clearly showed that the political drift was in the direction of socialization of medicine, and confirmed the tentative deductions made in these columns a week after the Paper was published. Although the political implications of the White Paper are those which are likely to arouse distrust in what is probably a predominantly conservative profession, doctors must take into account the generally favourable reception given by members of all parties in both Houses of Parliament to the present proposals for a comprehensive medical service. The more moderate organs of the Press, too, have welcomed the White Paper as embodying statesmanlike proposals for the reform of medicine. For example, the *Times* observes: "It is also necessary for all parties and interests to face the fundamental truth that, if the needs of the community are to be met, medical resources of all kinds, including general practitioners and specialists, must be available to different areas and different individuals according to their medical requirements and not according to their purchasing power. . . . No fair distribution of skill and resources is possible without some form of public planning. . . ." So if we may judge from the reactions of the Press and of Parliament the medical profession will get little public sympathy for any root-and-branch resistance to the White Paper proposals as a whole. There is, however, full recognition of the need for discussion on detail, and, we believe, a readiness on the part of Parliament to listen attentively to expert medical opinion on the many aspects of a contemplated legislative measure which, while not necessarily changing the face of medicine, bids fair to put a new and different complexion on it.

Mr. Willink, Minister of Health, said that the White Paper was built round four main principles which the Government believed to be fundamental: (1) comprehensiveness; (2) the freedom of the individual (no dragooning of patient or doctor into the service); (3) democratic responsibility—i.e., responsibility for the service to rest centrally and locally with the elected representatives; (4) the principle of professional and vocational guidance. Among the main features of the actual organization he stressed the principle of free choice of doctor (subsequently ridiculed by many of the Left-wing speakers): a desire to avoid regiment-

ation: no intention on the part of the Government to establish "a fully salaried State Medical Service"; no prohibition of private practice; apprenticeship for young doctors first entering on general practice; rationalization of the hospital services; and, lastly, "we have no doubt that the foundation of this scheme should be in local government." Mr. Willink was at pains to remove the profession's natural apprehensions about the meaning of the sentence at page 35 of the White Paper, which runs as follows: "The Board must also be able to require the young doctor during the early years of his career to give his full time to the public service where the needs of the service require this." One misapprehension arose from the fact that in the shorter version the word "when" appeared instead of the word "where": it should read "where" in both places. Mr. Willink then proposed an alternative phraseology, as follows: "The Board must also be able to require a young doctor entering the public service to give his full time to that service during the early years of his career in cases where the needs of the service require this." On the second day of the debate the Parliamentary Secretary to the Ministry of Health, Miss Horsbrugh, carried clarification a stage further by pointing out that it might not be possible for a young man to do part-time private and part-time public practice in a certain area; but this would not prevent his applying for such part-time work in other parts of the country. She instanced Mr. Willink's case of the young doctor wanting to work in Wakefield. His application for part-time work might be met thus: "We are short of doctors in Wakefield; therefore we must ask you to do full-time public practice. If you do not want to do full-time public practice, or full-time private practice, there are many other places in England and Wales where there are openings for doctors who want to do part-time private and part-time public practice."

The administrative proposals came in for much pertinent criticism, summed up in Lord Moran's phrase: "There is not one medical service, there are to be six. . . ." In spite of all the arguments in the White Paper, it cannot be said that the principle of comprehensiveness has been observed, and a Liberal speaker (Mr. Graham White) in the Commons regretted that the opportunity had not been taken to make "the Minister of Health really Minister of Health for the whole country, (and) giving him the control . . . of industrial health and also the school medical service." Mr. White also criticized the central administrative body—presumably meaning the Central Medical Board—as having a tendency to "become a close corporation and develop a Fascist tendency." In Lord Moran's view the functions of the Central Medical Board were more controversial than all the rest of the White Paper put together. The proposed powers of civil direction in time of peace were most unusual, and he thought it not irrelevant to ask the Government whether they intended to apply similar powers to other sections of the community. If the Board was to have the confidence of the profession, then some at any rate of its members should be elected by the profession. He thought that in order to avoid

splitting the profession into two the Central Medical Board should have a general practice section and a section for the consultant and specialist. The fears of the profession generally about the Central Medical Board were well expressed in the Commons by Dr. Morgan, and he voiced a common attitude when he said: "In all the services run by the Government there seems to be a blight to keep the doctors down and keep them [from] developing that initiative which they want to develop." He was afraid of the directionary powers of the Central Medical Board and wondered, for example, whether it might not send a young doctor into a bad practice, or into general practice when he might be better fitted to be a specialist. Not even the explanations of Mr. Willink and Miss Horsburgh about the fate of the young doctor of Wakefield could remove from the mind of Parliament the distrust felt towards the Central Medical Board. In Lord Dawson's words: "There is no body more in danger of becoming bureaucratic. . . ."

Health centres came in for their meed of praise and blame. The Government has its preference for paying health centre doctors by salary and for removing the competitive element among health centre doctors. This may be sound administration, but we doubt whether it is sound biology. Lord Moran considered that doctors who qualify after the war will prefer to work at health centres, and anticipated that "in no distant time the great majority of the younger men in the profession will be working in these health centres, working on salary because that is the means of remuneration proposed for the health centres." The result of this would be that the greater part of the profession would be removed from a life where rewards were conditioned by success in practice, and would be working in a service where rewards would bear little relation to professional success. "I think," he added, "it would be advisable to have some material stimulant to keep men on their toes." Nevertheless he thought that the centres would provide opportunities for work for the practitioner which had not existed in the past, and that they would make for greater efficiency. Reward for effort was also emphasized in the Commons by Dr. Howitt: "If you do not make a doctor's life attractive; if you do not allow him initiative and enterprise and a reward for hard and good work, you will not attract into the profession the people you want to attract."

The effect of the White Paper upon the position of the voluntary hospitals was discussed at length in both Chambers. Mr. Storey echoed the fears of many when he suggested that the White Paper proposals had been so framed as to make it possible at no far-distant date to acquire the voluntary hospitals and build them into a full State service. "The essence of a voluntary hospital," he observed, "is not its charitable funds but its tradition, its experience, the facilities it offers for independent experiment, independent research, and individual teaching, and also the opportunities which it offers for voluntary public service." There was little doubt in most of the speakers' minds about the effect of the new proposals on the financial stability of the voluntary hospitals. One member wanted to see grants to voluntary hospitals

administered in much the same way as a University Grants Committee makes payment to a university. Another member suggested that present members of contributory schemes should have the right "to earmark their taxation contributions, if they wish, for their hospitals contributory scheme." Fears for the finance of the voluntary hospitals are really fears for the control of these hospitals, because once the bulk of the money for the voluntary hospitals comes through local authorities—i.e., the new Joint Boards—they will insist upon a greater say in the control of the hospitals. In this connexion we would draw attention to remarks made by Dr. Howard E. Collier in a letter published in the *Supplement* of March 11. He asks: "Is the sole difference between a voluntary and a 'State' hospital the source from which its finances are derived? Has the voluntary principle contributed nothing of value to our hospitals except hard cash?" Dr. Collier suggests that the fact that a hospital is administered by a voluntary committee should not prevent it from receiving State money. What medical men wish to secure is professional freedom in a hospital, and this they get from voluntary administration. Such an atmosphere makes for full exercise of individual medical responsibility, and it is this which is of such importance for the patient. The principle of administration of the municipal hospital is different, and in the view of many discourages initiative and dampens the sense of responsibility on the part of the doctors working in it. As Lord Dawson wisely observed, "We do not place our claim for the voluntary hospitals merely upon sentiment."

The great merit of the White Paper is that it leaves plenty of room for discussion and negotiation, and Government spokesmen have already shown a readiness to take into full account the point of view of the profession on professional matters. The medical profession may well reflect upon the remarks made by Lord Samuel. The White Paper, he observed, "deals with one large part of what is the great political problem of our time." This problem was, how far State action should extend in industry, commerce, education, and health. In the nineteenth century this country had to deal largely with questions of constitutional reform and the establishment of full self-government. To-day the view of the country was that the part played by the State could not be decided according to the formula of individualism or the formula of socialism; there must be a combination of both. And this, we may add, would seem to be the line of thought behind the White Paper.

### LESSONS FROM THE BOSTON FIRE

When 114 victims of the Cocoanut Grove fire in Boston were brought to the Massachusetts General Hospital the staff were ready not only with an organization inspired by Pearl Harbour for dealing with a large influx of casualties but also with a clear-cut programme for the treatment of burns, on which two research projects were running at the time. The experience of the various departments of the hospital is recorded in a symposium of fifteen papers,<sup>1</sup>

<sup>1</sup> *Ann. Surg.*, 1943, 117, 801.

from which, out of a wealth of detail, a few facts of general interest emerge. As is to be expected when large numbers of people are subjected to the same physical violence, the injuries conformed to a pattern. The most obvious feature was the superficial burning, more extensive in women than men owing to differences in clothing; but of greater consequence were the accompanying respiratory lesions due to inhalation of flame or gases. The burns were of the type known as flash burns—i.e., brief exposure to high temperature—and the distribution of the burns bore striking testimony to the protection afforded by ordinary clothing against this kind of burn. Flash burns are common in warfare and often occur in circumstances in which respiratory complications are likely, so this aspect of the disaster is of special interest now. Although there was panic in the night club, none of the M.G.H. cases were found to have fractures. The conformity of the injuries to a pattern must not be forgotten if any attempt is made to compare the results of treatment with those obtained in other circumstances. In this connexion it is worth noting the speed with which the victims were got to hospital and the absence of treatment before admission.

Altogether 491 persons lost their lives in the disaster, and only 181 of the injured reached hospital alive, 39 of them dying later. The high proportion of dead to injured—of 114 victims brought to the M.G.H. only 39 were alive—clearly shows that there was at work some factor other than burning, which was for the most part superficial. This was early realized by the staff of the hospital, and the cherry-red colour of carbon monoxide poisoning was noted in some victims on admission. In view of the high death rate the paucity of post-mortem reports in the symposium is disappointing. It is true that a few are given in detail, but one gathers that only six were performed at the M.G.H. and a further sixteen in other parts of the city. If it is assumed that these are representative, the deduction follows that nearly all the fatalities were due to respiratory lesions—either burning of the air passages or asphyxia. There is nothing to indicate whether any of the asphyxial cases were of the type seen in the shelter disaster in this city. Of more practical interest than the asphyxial cases were those with burns of the air passages, for these presented a serious problem in treatment. An early observation was that patients with respiratory complications did not all respond to sedation with morphine. It is suggested that hyperactivity or even delirium may be due to cerebral anoxia, and two patients were promptly quieted by oxygen inhalation: for these patients morphine may be harmful. A few hours after the fire a number of cases developed dyspnoea, which had not been present on admission. This was attributed to the appearance of oedema in the respiratory burns comparable to that seen in burns of the skin. About twenty-four hours after the fire dyspnoea and cyanosis became worse in some of the cases, and in several tracheotomy or intubation was performed. Only two patients out of five treated by tracheotomy survived, and seven in all died in this stage. In three cases post-mortem examination showed that the lesions were too extensive to be relieved by tracheotomy—membranous inflammation extending into the smaller bronchi. The cause of this

change was in doubt, but it was thought to be the inhalation of toxic fumes. At a later stage the picture was of migratory atelectasis and emphysema due to obstructive bronchiolitis. One of the more important conclusions from this experience of pulmonary complications is that the degree of inhalation burn could not be ascertained immediately after the injury, and that the extreme oedema of the air passages that occurred in some cases was unpredictable. It is urged that great vigilance is needed for attacks of oedema even in patients with minimal surface burns.

The treatment of the surface burns consisted of no débridement, no cleansing, boric ointment dressings, and internal chemotherapy. In addition burns of the face, scalp, and extremities were bandaged with pressure. The dressings were not changed until the fifth to the tenth day, and in the case of superficial burns no other treatment was used. For chemotherapy sulphadiazine was given, and a previous observation that the concentration of drug in blister fluid of the burns follows closely that of the blood was confirmed. Thirteen patients were treated with penicillin by injection: most of these were cases in which the temperature remained raised after the sixth day. No claims are made for the value of this treatment, in which the dosage was afterwards thought to be too small. It is difficult to assess the results of the treatment of surface burns, but the staff of the M.G.H. thought them gratifying. Though bacteriological studies showed that most of the burns were infected, the second-degree burns healed without clinical evidence of infection and with minimal scarring. The deep burns remained unusually free of invasive infection. Whatever may be thought of this method as a routine treatment of surface burns, there is no doubt that in this particular disaster, with its high incidence of pulmonary lesions, it had great advantages. The minimal interference with surface lesions accorded well with the treatment of shock and asphyxia. It is to be hoped that information will be forthcoming about the fate of the 142 victims taken to other hospitals in Boston: 110 of them survived. There should be ample material for comparison with the experience of the Massachusetts General Hospital, whose staff have done real service in preparing this symposium.

#### PENICILLIN IN VENEREAL DISEASE

It is already well known that penicillin will cure uncomplicated gonorrhoea with a rapidity and certainty unapproached by any other form of treatment. This was to be expected from the *in vitro* observations made by the Oxford workers<sup>1</sup> in 1941: the gonococcus heads their list of pathogenic bacteria given in the order of their sensitivity to penicillin in culture. Clinical confirmation of this effect was first obtained in the U.S.A.,<sup>2</sup> and repeated in a small number of cases in the British Army in North Africa.<sup>3</sup> The necessary treatment for a man consists of a series of intramuscular injections over a period of about 24 hours and using not more than 100,000 units; the discharge ceases "like turning off a tap," and the usual tests for freedom from infection become and remain negative. It is obvious that under present conditions penicillin should not be used

<sup>1</sup> *Lancet*, 1941, 2, 177.

<sup>2</sup> *J. Amer. med. Ass.*, 1943, 122, 1217.

<sup>3</sup> *British Medical Journal*, 1943, 2, 755.

wholesale for this purpose; indeed, it is probable that even when the supply position has much improved penicillin should be reserved for sulphonamide-resistant cases. There are so many other unsatisfied demands for the drug that may be held to have a superior claim for reasons which include the actual saving of life, that even this limited concession may occasion misgiving until supplies are adequate for all purposes. It is now announced that penicillin can also be used for the treatment of syphilis. Preliminary studies of the treatment of the disease in rabbits having given encouraging results, the investigation has now been extended in the U.S.A. to man, and Mahoney, Arnold, and Harris<sup>4</sup> report on the effects in four cases. These were all men with chances of eight to ten days' standing. They had no treatment except intramuscular injections of penicillin, each dose containing 25,000 units, given 4-hourly day and night for 8 days, the total dose thus being 1,200,000 units. Some malaise and slight fever were produced, and the chancre became painful and the inguinal lymph nodes enlarged and tender. Dark-ground microscopy was employed at 4-hourly intervals from the start of treatment to study the effect on the organism: no *T. pallidum* could be found after sixteen hours. No fewer than seven qualitative and three quantitative serological tests were used to follow the progress of the disease, and, with a few doubtful exceptions in one case, all became negative, usually some weeks after the treatment was complete. It is of course intended to watch these cases further, and very prolonged observation of a much greater number will have to be carried out before the treatment with penicillin even of primary syphilis can be accepted as efficient. On possible actions at later stages there is no information at all. It will, of course, be of immense advantage if a course of only eight days even of very arduous treatment should prove to be effective, and it will certainly be safer than any other form of intensive treatment, since penicillin has never been known to have any serious toxic action. Who would have supposed that both venereal diseases would ever be curable by the use of a single remedy?

### DIGITALIS IN CONGESTIVE HEART FAILURE

Although the use of digitalis for the treatment of heart disease was due to Withering, one of our own countrymen, it has been left to those elsewhere to make the fullest use of it, for even to-day digitalis and the digitalis glycosides, such as digoxin, are scarcely ever given to patients with heart failure when the rhythm is normal. As a result of the work of Mackenzie and of Lewis digitalis is reserved for the heart failure which follows auricular fibrillation, a failure due not to any weakness of heart muscle but to a disordered rhythm. Like any other pump, the left ventricle cannot eject fluid unless there is time for it to fill between each stroke. If the impulses come from the auricle too quickly, as when the auricle fibrillates, the output from the ventricle is poor, no matter how powerful the ventricular muscle may be. Digitalis and its glycosides restore the normal output by depressing conduction from the auricle to the ventricle and so reducing the number of impulses which reach the ventricle. The ventricular rate is slowed, and the ventricle has time to fill. Digitalis, however, has another action: it increases the force of contraction of the cardiac muscle. When this action is demonstrated on a normal heart muscle it is small and not impressive; in muscle which is damaged, however, it is much greater. It should be the duty of every teacher of pharmacology to show his students how strophanthin increases the cardiac output in a heart-lung preparation in which the ventricular muscle has first been weakened by

a barbiturate. This demonstration is important, because it is the basis of the use of digitalis in patients with failure in whom the rhythm is normal.

Recently S. Berséus,<sup>1</sup> working in Stockholm, has determined the effect of glycosides of strophanthus and of digitalis on the cardiac output of normal individuals and of patients with congestive failure. In conformity with results in animals he observed very little effect on the cardiac output of the normal subjects, but in the patients he was able to demonstrate the increased output with certainty. He used a Danish preparation of digitalis called digiton, injecting 2 c.cm. intravenously. This is equivalent to 2.6 c.cm. (or 40 minims) of standardized tincture of digitalis. In one group of patients the mean of the initial values for the cardiac output was 1.97 litres per minute. One hour after injection this rose by 19%; after two hours it was still 15%, and after two and a half hours 8%, above the initial value. A similar result was achieved in one patient in whom there was no disorder of rhythm and who had a slow heart rate. This was a case of mitral stenosis and insufficiency, with pronounced decompensation and a heart rate of 52 per minute after fourteen days without digitalis. When the injection was given the cardiac output rose from 2.32 litres per minute to 2.59 after two hours. The patient improved considerably with digitalis and diuretics. In these patients there was not only a rise in the cardiac output but also a fall in the arteriovenous oxygen difference; with the improved circulation the venous blood arriving at the right side of the heart was not so reduced. The decrease in the arteriovenous oxygen difference was 15% at its maximum. These results bring to memory the efforts of the late A. Fraenkel to popularize the use of strophanthin<sup>2</sup> for patients with heart weakness and normal rhythm. Strophanthin, which in the *B.P.*, 1932 is a standardized preparation of uniform potency, is given intravenously, and has a similar action to digitalis, but it is not cumulative, so that the injection can be repeated every other day. Fraenkel used 1/240 grain (or 0.25 mg.). One of his more remarkable charts<sup>3</sup> showed the loss of 15 lb. oedema fluid in a patient to whom he gave strophanthin, despite the existence of arteriosclerosis, a heart rate of 40 per minute, and complete heart-block.

It is probable that there are many patients who after an attack of pneumonia or bronchitis continue to suffer from congestion at the base of the lungs for some time. A careful trial of digitalis in the form of leaf or tincture, or as the crystalline glycoside digoxin, should certainly lead to more rapid disappearance of the congestion. Berséus also made observations on the effect of theophylline diethanolamine on the cardiac output and of nikethamide (coramine) and leptazol (metrazol or cardiazol). None of these substances affected the cardiac output of patients with congestive heart failure, and the only substance which produced any effect at all was theophylline, which in a dose of 0.2 g. given intravenously caused a slight increase in the oxygen consumption. It is excellent to have clinical evidence from patients with heart failure that these substances do not act as cardiac stimulants.

Dr. H. Guy Dain, Chairman of Council of the British Medical Association, will receive the honorary degree of M.D. from the University of Birmingham at a special congregation in July next.

Dr. R. W. Craig, Scottish Secretary of the B.M.A., is one of the newly elected Fellows of the Royal Society of Edinburgh.

## TEACHING AND RESEARCH IN OPHTHALMOLOGY

BY

Sir JOHN HERBERT PARSONS, D.Sc., F.R.S., F.R.C.S.

Recent discussions and correspondence reveal some confusion of thought among ophthalmologists with regard to the rôles of teaching and research. This confusion seems to permeate the discussions and planning of medical education in general. It may therefore be worth while to analyse the concrete example of ophthalmology. Before doing so, however, certain general principles of medical education should be stated and be firmly kept in mind. The primary functions of the medical man are the alleviation and prevention of bodily ailments; and, important though research may be, it is not derogatory to it to assert that, so far as the practice of medicine is concerned, it is ancillary and secondary to those great primary functions. Of course, medical research may be carried on as a branch of pure science, but too great stress upon this aspect is not free from danger in dealing with medicine as an applied science. As an example one may point out that physiology has tended more and more to become a pure science, relatively independent of medicine; and however beneficial to medicine this may ultimately be, it does not appear to have been immediately beneficial to the teaching of medical students.

In his excellent article on "Some Principles of Reform in Medical Education" (*B.M.J.*, 1944, 1, 173) Dr. F. M. R. Walshe, after reference to the universal dissatisfaction with the present curriculum, says: "It is the fundamental defect of our teaching that we have not given the student a firm grasp of general principles, we have not taught him to weigh evidence, to discriminate or to think logically, and we have too often failed to imbue him with that keen desire for understanding that is the essence of true education. We have been content to preoccupy him with feats of memorizing and with the acquisition of an increasing number of techniques." He summarizes the essentials of reform as follows:

"(1) A carefully thought out pruning of the amount of factual knowledge we seek to impart, ruthlessly undertaken in order that

"(2) the student may be enabled to develop a more thoughtful and critical attitude, and a deeper understanding of the causes and manifestations of disease.

"(3) An explicit recognition of the necessity of a leaven of theoretical medicine, side by side with its vocational aspects, and the provision of a category of teachers who shall develop it."

In an article on "Medical Education of the Future" (*Lancet*, 1940, 1, 420) I expressed the opinion (1) that the teaching and curriculum for the qualifying examination should be designed to produce the best type of general practitioner;

(2) that the teaching hospitals should cater for both undergraduate and postgraduate students. So far as I have been able to gather from conversations with members of the various planning organizations, the first principle has been definitely accepted, but I have been able to obtain no evidence that the extremely difficult task of initiating radical changes in the teaching and curriculum which this reform demands is being embarked upon. As Dr. Walshe remarks, "In addition to this rebuilding of the very foundations of medical education, there can be no doubt that an urgent need is a quite ruthless pruning of the range and amount of factual knowledge we expect of the student."

### The Teaching of Ophthalmology

Applying these general principles to the teaching of ophthalmology, it is immediately apparent that this specialty is essentially a postgraduate study, and that the undergraduate student should be taught only those parts which are necessary for a general practitioner—e.g., the diagnosis and treatment of external diseases, the use of the ophthalmoscope, and, last but not least, when to call in the help of an expert. This course will be best carried out in the ophthalmic department of the general hospital.

It is unnecessary to deal here with postgraduate teaching. Except to state that medical ophthalmology should receive more attention than at present and that it would be best carried out

in an eye hospital, and most efficiently in one closely related topographically and corporately with a general hospital. The regional distribution of medical teaching which seems likely to obtain in the future will facilitate such a scheme. Each region should have its ophthalmic institute incorporated with the central teaching hospital and school. Two such institutes would suffice for London: one in the north, near University College, formed by the amalgamation of Moorfields, the Central London, and the Western Ophthalmic Hospitals; the other in the south, near King's College Hospital, formed by the amalgamation of the Westminster and the South London Ophthalmic Hospitals. Other such units should be established in the large provincial towns.

### Research in Ophthalmology

When one considers research in ophthalmology it is equally necessary firmly to bear in mind certain general principles. Here again the fundamental principles have been clearly set forth by Dr. Walshe in his article on "Strategy and Tactics in Research" (*B.M.J.*, 1943, 1, 467). While it is impossible and most inexpedient to divorce so-called "basic" from "clinical" research, there is sufficient disparity between them to justify considering ophthalmic research under these headings.

*Clinical research* has long flourished in eye hospitals, and should be encouraged in every way, financial and otherwise. It should not, however, in my opinion, be under the control of a whole-time professor, except in the very rare instance of the advent of a man specially endowed by temperament, originality of thought, skill, and training (see below).

"Basic" research—the investigation of the nutrition of the eye, intraocular pressure, glaucoma, cataract, etc.—demands a knowledge and a training which few ophthalmologists possess. Such notable exceptions as Donders, Leber, Priestley Smith, and, more recently, Duke-Elder and Mrs. Dorothy Campbell, are *rarae aves*. Such research requires extensive, profound, and up-to-date knowledge of many branches of pure science—physics, chemistry, biochemistry, and so on—together with prolonged training and familiarity with laboratory techniques. These attainments are more likely to be found among young physiologists than among ophthalmologists. As Dr. Walshe so well says, "No planning can provide us with these men or determine the goal of their labours"; and again, "It is round the man and not round the plan that the wheels of research revolve most rapidly." This all-important fact was clearly recognized by Sir Walter Fletcher, and the phenomenal success of the Medical Research Council probably owes more to it than to any other. Encouragement, opportunity, financial assistance, and a free hand to a man who has shown originality, skill, perseverance, and enthusiasm in research may well eventuate in "a sort of spontaneously arising organization that has grown round a personality and has owed little or nothing to deliberate planning. When this comes into existence it is the richest of all sources of original knowledge" (Walshe).

### The Research Professorship

It is a fallacy, only too prevalent at the present time, to imagine that the lavish endowment of whole-time *ad hoc* professorships and their multiplication will solve the problem of research. It does not follow that this is not the ideal method of procedure in appropriate conditions. The most important of these are (first and foremost) the man; and then intimate association with other research workers, especially those engaged in ancillary sciences; and, of course, adequate facilities.

For reasons already stated, the most suitable man is likely to be found among the younger physiologists. Dr. Lythgoe was an outstanding example of the success of nursing up and ensuring an adequate livelihood for a young physiologist interested in visual problems. But for his untimely death he might well have founded a school of research. Even he was lacking in clinical ophthalmic experience. I thoroughly endorse the opinion of Dr. Walshe: "I cannot believe that any medical research worker can afford to divorce himself from clinical studies. When he does so he invariably loses touch with reality."

The qualities required for a "basic" research professor in ophthalmology are exacting. The Medical Research Council have been fortunate in obtaining Dr. Hallpike as head of an

otological research unit, and I have reason to think that they would be prepared to institute a similar ophthalmic unit if a suitable man could be found. If found among the physiologists it should be made a condition of his grants that he should obtain clinical experience in an ophthalmic centre. In the meantime it would be wise to devote financial support to grants in aid of clinical and basic research, and to defer the appointment of a whole-time professor until a suitable clinician or a suitable basic research worker is discovered.

Some reference should be made here to the Oxford Ophthalmological Research Endowment scheme. The conditions at Oxford fulfil most of the requirements for a whole-time professor. There is an eye hospital next door to a large general hospital. All the facilities of the University science laboratories are available, and these provide the requisite "atmosphere" of research. Moreover, the senior surgeon to the eye hospital, Miss Ida Mann, is of proved skill as a research worker. One has here the nucleus of an ophthalmic research institute which more than any other at the present time justifies support.

## Reports of Societies

### SINUS TROUBLE IN CHILDREN

At the Royal Society of Medicine on Feb. 25 a discussion was held on sinusitis in children.

Mr. H. BEDFORD RUSSELL said that failure to detect sinusitis after the infections of childhood might condemn the patient to a long train of apparently unrelated diseases. The earlier the treatment of sinusitis the greater the hope of achieving complete cure. The vicious circle of swelling, lack of ventilation, and more swelling must be broken. The indication was to reduce the swelling and introduce some harmless vasoconstrictor to every available part of the mucous membrane. Medical men were disinclined to use cocaine because of its habit-forming properties, but he had not met with addiction after its use in the nose. The risk of absorption through the mucosa was reduced by mixture with some vasoconstrictor. In children with sore noses it was important not to use the speculum unsupported. Nor was it desirable to use the spray with the patient supine; if the patient would not sit up the head should be turned to one side so as to avoid the need for tilting the spray. He demonstrated on a small patient his palliative displacement method. Though the aim of displacement was simply the introduction of fluid, its use was often immediately justified by the avoidance of a huge blob of mucus. In judging the results of displacement note should be taken of the cessation of nasal breathing and relief of headache.

Mr. S. E. BIRDSALL said that the developmental continuity of the nose, sinuses, and middle-ear led to the logical conclusion that sinusitis was likely to be just as common as otitis media in children. It was not so regarded because of three obvious corollaries in middle-ear disease which made its recognition easy and were not found in sinusitis in children—namely, pain, loss of function, and visible external disease. In adults sinusitis might exist without any appreciable formation of pus. The essential in diagnosis was anterior rhinoscopy. In 80 cases of indisputable sinusitis in children, the clinical features of which he had tabulated, the aetiology was hard to assess, and in only 13 was there good evidence of antecedent cause. Of specific infections, unless the common cold was regarded as such, whooping-cough was the most common. The important symptoms in these 80 cases were, first, nasal obstruction, and, secondly, cough. Cure of sinusitis in children depended only on recognition of the disease. Ephedrine was very often successful. Operation was necessary in fewer than 10%.

Mr. A. WELLS held that defective respiration was the root cause of a great number of cases of sinus trouble, particularly in children. The blocked nose meant increase of pathogenic organisms in the nasopharynx. Most infants breathed perfectly freely through the nose in spite of the fact that the adenoid tissue in the nasopharynx was present at birth. At some stage the child developed a cold in the head and became for the time a mouth-breather. In due course resolution took place

and the tissues returned to normal, but in a proportion the mouth-breathing continued as a habit or a necessity. He recommended the simple treatment of diastolization as being likely to prevent the need for a great deal of after-treatment. The apparatus consisted of hollow rubber bougies of various sizes, shaped to adapt to the nasal canal. By compression of a bulb the bougie dilated. Saline solution was introduced into the nose, and a massage of the nasal mucosa was brought about. Out of over 2,000 children with defective hearing severe enough to fail in the test on three consecutive occasions, 57% improved after a course of diastolization sufficiently to enable them to pass the test.

Dr. W. GUNN said that he had searched the records of fever cases at the North-Western Fever Hospital in a recent year and found sinus infection only in 8 out of just over 2,000: 5 of these 8 were associated with infectious diseases, 3 of them being measles.

Dr. R. CRUCKSHANK said that the cases of sinusitis he had seen were cases which had defeated both physician and surgeon and had come as a last resort to the bacteriologist in the hope that some vaccine might be found. He uttered a word of warning about *Staph. aureus*, which was present in the nasal cavities of from 60 to 80% of children; therefore the discovery of it in the nasal swab did not necessarily mean infection in the nose or associated sinuses. It was remarkable how frequently the patient did not refer the symptoms to the sinus. Persistent sore throat, headache, general mental weariness, and recurrent attacks of pneumonia might be associated with the primary focus in the sinus. On the bacteriological side of this problem the nasal carrier as a possible source of infection should not be forgotten. If examination was confined to throat swabs, more often than not the actual source of infection would be missed.

### A Question of Terminology

Mr. T. B. LAYTON asked what was sinusitis. What would be thought of the Section of Medicine or the Association of Physicians if they spent two solid hours talking about "rheumatics"? Yet it was something corresponding to that that Mr. Bedford Russell and Mr. Birdsall had done. They had lumped together a number of different pathological conditions under the term "sinusitis." Pus in the sinuses was, in his opinion, rare in children. When it did occur it was very difficult to eliminate. He had still under his care a girl aged 20 who developed it after either scarlet fever or measles at the age of 5. The nasal cavity was even yet not quite free from pus, but during the interval she had developed normally in mind and body, and had none of the numerous disabilities which were said to be attributable to sinusitis. Early in the 'twenties it became appreciated that instead of polypi in the nose being secondary to sinusitis, there was a polypoid reaction in the lining of the maxillary and other sinuses. Presumably that reaction was inflammatory, and one could rightly apply the term "sinusitis" to it, but when there were two distinct lesions to which the same term was applied it was well to use a qualifying adjective. Polypi were not common in children; in the rare cases in which they occurred they were secondary to a suppurative reaction in the sinuses on which the original teaching was based. The sinuses were involved in the great majority of cases of rhinitis, and he thought this rhino-sinusitis should be treated on physiological principles, the first object being to restore nose-blowing as the swelling of the mucous membrane in the acute invasive stage began to pass away. He urged that before children were discharged from a fever hospital the nurse should take care to establish nose-blowing. This would be of greater value "than all the cultures and swabs in the world."

A meeting of the Joint Tuberculosis Council was held at the London School of Hygiene and Tropical Medicine on Feb. 19, with Dr. James Watt in the chair, when among much other business the following resolution of the Tuberculosis Association was reported: "The Council of the Tuberculosis Association be instructed to approach the Councils of the J.T.C. and the N.A.P.T. with a view to a joint request to the Minister of Health to make B.C.G. available for trial in this country." In the discussion which followed Prof. W. H. Tytler expressed the view that, if an investigation was asked for, the general use of B.C.G. would be delayed for a considerable period. Though the majority of members were of the

opinion that B.C.G. should be made available for the inoculation of selected tuberculin-negative persons, no formal change was proposed in the terms of reference, and Prof. Tytler and Dr. Wilfrid Sheldon agreed to represent the Joint Tuberculosis Council in the deputation. The following officers for 1944 were elected: chairman, Dr. James Watt; vice-chairmen, Dr. P. Sutherland and Dr. N. Tattersall; hon. treasurer, Dr. A. P. Ford; hon. secretary, Dr. Norman England. The Council recorded appreciation of the very valuable services rendered by the retiring officers: Dr. J. B. McDougall as hon. secretary, and Dr. G. Jessel as hon. treasurer.

At a meeting of the Manchester Medical Society on March 1 Dr. A. A. Moncrieff gave an address on "Some Disorders of the Newborn Baby." He indicated first the importance of the subject, since the death rate among the newborn had not been reduced and represented a loss of life which was serious. Organized effort in other parts of the world, notably Chicago, had effected a great reduction. Much of the trouble arose from the way in which people regarded diseases of the newborn as rather mysterious. Just as paediatrics was general medicine at a special age period so diseases of the newborn were largely problems of applied physiology and pathology at the beginning of life. Dr. Moncrieff dealt first with problems of respiration, showing how the work of Adrian and of Barcroft had cleared up many problems. Respiratory failure was most commonly due to obstruction or to depression of the respiratory centre. Next he dealt with head injuries in the newborn, pointing out how their management was the same as in adult patients, and he stressed the value of hypertonic saline per rectum. Finally he dealt with some of the problems of infection in the newborn baby, stressing the need for research into many aspects of immunity at this age period. In reply to a question he gave a brief survey of the influence of the Rh factor on the mother and foetus.

## Correspondence

### Reform in Medical Education

SIR.—In his admirable paper on this subject (Feb. 5, p. 173) Dr. F. M. R. Walshe discusses the peculiar situation which has resulted from the rise and spread of specialization in medicine. Medical education, it would appear, is in danger of becoming a mere vocational training. The student spends years in amassing numerous facts relating to the various special branches of medicine, yet he may remain unable to weave these tangled threads into one coherent fabric of knowledge.

This problem has been recognized in high places, and one plan for its solution, now under trial by military and civilian authorities alike, has been the introduction of the psychologist into the scheme. Apparently it is felt that, although by this action the services of yet another specialist are enlisted, the psychologist, encountering the patient who, for better or worse, has passed already through the hands of experts in other departments of medicine, will focus attention upon the man himself rather than upon his individual organs. As for the present, any tendency on his part towards an incoherent or disconnected conception of medicine may be counteracted, it is hoped, by the wider vision revealed to him by a study of psychology, normal and abnormal.

Unfortunately, this solution of the difficulty is not fulfilling all the hopes of its promoters. As Dr. Walshe remarks, psychological medicine is still "highly charged with controversial matter." He goes on to suggest as the essentials of reform in medical training, first, a careful pruning of the curriculum; and, secondly, the introduction of what he terms "a leaven of theoretical medicine." A closer attention to the theory or the first principles of medicine would presumably supply to the student some of that philosophical outlook which Claude Bernard sought to impart to readers of his classic work *The Introduction to the Study of Experimental Medicine*. Some such fundamental "grounding" must strongly appeal to those who view with alarm the ever-rising tide of specialism. But where is this basis of medical theory to be found? Probably not in psychological medicine, nor, indeed, in any medicine of to-day, so sadly decimated and fragmented by the specialists. Not to the present but to the past we must look—to that past so often derided as useless and obsolete—if we wish to study first principles in their correct perspective.

In his recent address to the Royal College of Physicians Churchill, confessing himself to be a great admirer of

tradition, remarked that, "*The longer you can look back the further you can look forward.*" His words might well be adopted as a slogan by those responsible for medical education. There is much to be said for a "return to Hippocrates," warmly advocated a few years ago by those who saw danger in the present-day trend of medicine. They hoped that the entire patient, and not merely a small part of him, would occupy once more the centre of the picture. There might even be justification for the reinstatement of the "Aphorisms" as a students' textbook. But medicine has had a long and varied career since the "Father of the Art" held his clinics under the plane-tree of Cos, and nothing less than a complete conspectus of medical thought and practice throughout the centuries will furnish that theoretical foundation which modern medicine so sadly lacks. Sir William Osler was of opinion that "by the historical method alone can many problems of medicine be approached profitably." Nevertheless, at the present time none of the medical schools of our country is providing systematic instruction in the history of medicine for its students. "It is a dry age," continues Osler, "when the great men of the past are held in light esteem." Have we arrived at that "dry age" so far as medicine is concerned? If we have, the remedy is obvious.—I am, etc.,

Edinburgh.

DOUGLAS GUTHRIE.

### Prevalence of Ketosis among Children

SIR.—For some time it has been apparent that an increased number of children have been seen in this area with the signs and symptoms of faulty fat metabolism. As shown by routine testing of children's urine for acetone bodies (Rothera's test) a large proportion are suffering from some degree of ketosis.

It is well recognized that acute infections may be accompanied by acetone bodies in the urine, and that in certain types of children nervous or physical exhaustion (over-excitement or violent exercise) may have the same effect, as may vomiting from any other cause. It seems, however, that at the present time the majority of children examined have acetone bodies in the urine.

The commonest symptoms and signs are anorexia, headache, hollow-eyed appearance, bad breath, pyrexia, abdominal pain, and vomiting. The vomiting may be absent, slight, or repeated. The pyrexia may be as high as 104° F. without any sign of infection, and the abdominal pain severe enough to suggest the possibility of acute appendicitis. In differential diagnosis it is necessary to exclude diabetes, organic disease of the brain and kidneys, and appendicitis. As regards treatment, the alteration of the diet to low-fat high-carbohydrate, and the regular administration of glucose, together with an alkaline mixture or "alkazanc," have a beneficial effect in nearly all cases. The following are cases illustrating different types.

M. H., aged 6, for two years had had sudden pyrexial attacks, often unaccompanied by vomiting, though this had occurred on one or two occasions. Urine in all attacks gave a strongly positive reaction when tested for acetone bodies. Skimmed milk, reduction of fat, and regular glucose diminished but did not entirely remove these attacks. Finally no milk was allowed at all, and "alkazanc" was given. So long as this regime was followed he remained free from attacks, but on the introduction of even a small amount of milk they recurred.

P. M., aged 3, had been "off colour" for several months with a poor appetite and general debility and loss of weight. Alteration of diet produced rapid and lasting improvement.

R. T., aged 12, was a new child to the district (urgent evening call to suspected appendicitis). The history was that the family had moved that day and the boy had taken an active part in helping to arrange furniture in the new house. He was highly intelligent and was said to have been very excited by the move. He complained of severe abdominal pain, had vomited several times, and his temperature was 99.8° F. There was no localized tenderness and the urine gave a strongly positive reaction for acetone bodies. Next day no symptoms—out for a walk.

The chief contributing factor seems to be the natural tendency on the part of mothers to fill up children with a poor appetite with milk and such other dairy products as are obtainable. The rationing of sugar and the diminished sweet consumption also probably play a part in predisposing to ketosis.—I am, etc.,

F. B. P. EVANS.

Tewkesbury.

### Nervous Breakdown in the Navy

SIR.—I have read with great interest Surg. Lieut.-Cmdr. G. Tooth's article on nervous breakdown in the Navy (March 11, p. 358) and his interesting discussion of the significance of domestic difficulties. His tables appear to show one point which he has not emphasized—namely, that the bad prognosis of those cases where domestic difficulties were found to be the main cause is explained by the proportion of such cases in which this factor was one of multiple causes: the proportion inviolated where domestic difficulties alone was the main cause (24.4%) appears to be intermediate between that for enemy action (29%) and that for conditions of service (22.6%). It would perhaps be surprising to find in wartime that domestic difficulties were a more important cause than enemy action or conditions of service (out of a total of 284 cases in Table I there were 58 with domestic difficulties as a main factor). Such considerations, however, do not alter his conclusions concerning the need for social services, since "domestic difficulties" is presumably the only one of the three factors he has studied which can be tackled.—I am, etc.,

Birmingham.

RUSSELL FRASER.

### Vaginal Ulceration and Vitamin C Deficiency

SIR.—*Odium albicans* and *Trichomonas vaginalis* were examined for as part of the routine investigation of all cases of vaginitis attending the gynaecological clinics referred to in the article on vaginal ulceration and vitamin C deficiency which appeared under our joint names in the *Journal* of Feb. 19 (p. 254). Both conditions were excluded in the cases quoted in this article, but this was not expressly stated, as in neither case was the vaginal discharge characteristic of an infection with *Odium albicans* and *Trichomonas vaginalis*.

We agree with F. B. Chisholm (March 4, p. 338) that where *Odium albicans* and *Trichomonas vaginalis* are not responsive to their specific treatment it may well be that vitamin C deficiency may be the underlying cause. This can be supported by cases we have seen, where secondary infections of syphilitic ulceration and gonococcal vaginitis have cleared rapidly with large doses of ascorbic acid.—We are, etc.,

M. K. LAWLOR.

### Gold Treatment of Chronic Arthritis

SIR.—May I congratulate you on your excellent and very timely leading article on gold treatment (March 4, p. 329). Your endeavour to clarify the issue must be deeply appreciated by anyone who, like myself, day by day observes on a very large number of patients how widespread—I would even say indiscriminate—has become the use lately of this not so indifferent drug. I have seen not only many cases of typical osteoarthritis but even a case of chronic lumbago that had been subjected to this treatment. Having been among the first—if not the very first—to employ gold (Möllgard's original sanocrysin) for the treatment of various types of arthritis nearly 20 years ago, I discovered that this drug has a very limited usefulness, and in a certain type of rheumatoid arthritis only.

Some years ago in a booklet (*Der Gegenwärtige Stand der Rheumafrage*, originally an anniversary lecture to the Czechoslovak Medical Association at Bratislava and published by that association in 1937) I said:

"As to the gold injections so generally used lately, after thorough serial experiments carried out on several hundreds of patients I came to the conclusion that their use should be restricted to those cases which are undoubtedly of infectious origin, the infection still being more or less active and the virulence being clearly shown by small, if even minimum, rises of the body temperature. In such cases it will be always possible to break the acute tendency of the disease and bring about an improvement of the defensive power of the organism, thus preparing the soil for the successful employment of other healing principles. Although by a very careful application of the injections it is nearly always possible to avoid any serious damage to the organism, yet such damage can and does occur, and I would like to utter a serious warning against the stereotyped use of these injections."

May I add to this that the cases of rheumatoid arthritis referred to belong to a definite type. In your *Journal* on March 24, 1928, I described the exact nature of this type of

articular rheumatism. The therapeutic suggestions made there have undiminished validity even if gold treatment is carried out simultaneously.

In order to achieve a higher concentration of the gold in the synovial fluid without increasing the total amount incorporated into the system of the patient, I am at present trying to introduce electrically dissociated gold ions direct into the various joints with the help of iontophoresis. My experiments are far from complete yet, but so far they seem to be promising. I hope to be able to publish the final results later on. Meanwhile much useless suffering and unnecessary expense to patients and serious disillusion to doctors could be avoided if doctors would take your well-founded warning to heart and would seriously scrutinize their cases before submitting them to this treatment.—I am, etc.,

Newark.

L. SCHMIDT, M.D. Prague.

SIR.—May I, with all due deference, refer to one or two points in your recent editorial on the treatment of chronic arthritis by gold. The profession has, I believe, come to regard such articles as valuable reviews upon different subjects compounded by authoritative specialists. Hence I feel that some comment upon this article on the treatment by gold should be made, in order that a truly fair and comprehensive review may be achieved.

In the first place there is no mention of an exactly similar investigation published eight years ago by Koppenhofer, who came to almost identical conclusions as those in the article to which you have referred by Freyburg, Block, and Levy. He does, however, make an additional and interesting observation that the situation in which the gold is deposited changes most significantly—in that in the normal animal gold is deposited in the parenchymatous cells of the liver, while whenever there is infection present in the body then the gold is deposited in the reticulo-endothelial system, and he cites similar differential deposition in the cells of the lung with and without the presence of tuberculous infection. Koppenhofer further pointed out that gold aurothiosulphate salts are broken down within the body to the sulphide, which (as I have always understood it) was the reason for using gold sulphide *ab initio* as a therapeutic substance.

Your article does, however, reach the essential point in one phrase: "... since it is still unknown where, how, and why gold salts work." This is the crux of the whole matter. There is surely a good deal of evidence that the action of gold is necessarily upon the functions of the liver and reticulo-endothelial system. Koppenhofer subscribes to the view also held by Feldt that the action of gold "is of importance in the biological stimulation of the natural defences of the organism... as an activator of the proteolytic ferments accelerating the disintegration of toxic substances." This would seem contrary to your editorial statement that the only possible action of gold is to lessen or arrest inflammation, though it is not stated just how. Personally, from clinical pathological experience I have always considered gold, especially when deposited in the metallic form, as having many possibilities as a biological catalyst. From the clinical point of view there is no doubt that some physiological action can be attributed to intramuscular injections of colloidal gold sulphide, and if it may be expected that the action is a catalytic one in the reticulo-endothelial system there would seem to be no reason to doubt that the usual chemical laws in relation to catalysts would not be operative.

I suggest that it would only be a fair judgment to acknowledge that clinical therapeutic effects are noted in this country as a result of the injection of gold sulphide, and also to acknowledge or recognize the earlier work of the late Koppenhofer with such very similar results. I feel certain that your suggestion that rheumatoid arthritis is "an active inflammatory condition" is a red herring which it is probably wisest not to drag any further at this juncture, nor, indeed, the question whether thiomalic acid is an inorganic compound.—I am, etc.,

London, W.1.

HARRY COKE.

SIR.—In a leading article of March 4 on the treatment of chronic arthritis with gold you speak of the conspicuous lack of carefully controlled observation in the treatment of rheumatoid arthritis by gold until the recent research by Freyburg,

Bloek, and Levy and the work of Sabin (*Proceedings of the Mayo Clinic*, 1942). Your attention should perhaps be drawn to some significant British work, published in 1937 and 1938, by Hartfall, Garland, and Goldie (*Lancet*, 1937), and by Ellman and Lawrence from the Rheumatic Unit at St. Stephen's Hospital, L.C.C. ("Gold Therapy in Rheumatoid Arthritis, with Controlled Experiments"), and by Gasking from Harrogate, these two papers appearing in the *Reports on the Chronic Rheumatic Diseases*, Vol. 4, 1938, to which full reference is made in recent American works on "chronic arthritis." It is regrettable indeed that the White Paper makes no special mention of the rheumatic diseases.—I am, etc.,

Great Bookham, Surrey.

RICHARD A. MANCLARK.

### Familial Anaphylactic Death

SIR.—In your issue of March 4 (p. 331) you use the adjective "familial" preceding the word "allergy," and I must say I like it, though "familial anaphylaxis" would be better. Nothing separates these sudden deaths in persons sensitive to the protein injected from the experimental anaphylaxis of the guinea-pig except this peculiar tendency to a family history of the same or other allergic complaints.

In 1,000 consecutive cases of familial allergy a history was obtainable in 567 cases of asthma or similar complaint. In 1,000 non-allergic cases there was a family history in 422. So that asthma as a whole bears this familial trait almost as much as the allergic side of it.

Happily I have not seen such a fatality myself, probably from the small doses used and the amount of adrenaline given with them, but there are plenty in the literature. Samson quotes 40 deaths from horse-serum content in antisera. He reckons that 1 to 70,000 children may be expected to die in this rapid anaphylactic manner if it is given without the fullest precautions. The nearest approach I ever had was when giving to a very severe case of asthma in a young woman four minims of a 5% solution of peptone intravenously. Her respirations at once became more and more difficult, she became blue in the face, speechless, and then unconscious, her chest being in an inspiratory spasm. She passed water—a typical anaphylactic symptom. Ten minims of adrenaline intravenously gradually brought her round, her pulse rate being little affected during the shock. Perfectly well next morning she went to work and was free from asthma for five weeks.

Deaths have occurred from intradermal test injections, so that the puncture test or scratch tests are preferable, and always so with pollen. Using a control this is an easy way to avoid these sudden deaths, if one were at all nervous about any particular case—that is, its degree of sensitivity. I am sorry there was no greater attempt made to find out how it was that the girl mentioned in your annotation became sensitive to guinea-pig serum, nor does the original American paper help us.—I am, etc.,

London, W.1.

FRANK COKE.

### Chloroform Anaesthesia

SIR.—Dr. W. H. Spoor (March 11, p. 374) has not been able to adduce a more cogent argument in defence of the use of chloroform than did John Snow, who, believing ether to be safer, justified his use of chloroform on the grounds that "an occasional risk never stands in the way of ready applicability." His implication that "the expert" has abandoned the "rag and bottle" in favour of the offspring of an oil refinery and a B.B.C. transmitter merely to satisfy an unreasoning urge to play with lovely toys is misleading. Many anaesthetists of consultant standing are quite as expert chloroformists as any G.P., however old, and have to their credit as many administrations without a fatality. Why, then, have they virtually discarded an agent possessing so many advantages?

I only know my own reason, which was that the continued failure of the Angel of Death to appear had little or nothing to do with my skill but a lot to do with my luck, and that the latter might not hold out indefinitely. Or, to use the words of the A.M.A.: "The use of chloroform for major operations is no longer justifiable. Scientific investigation and clinical experience agree that necrosis of the liver (chloroform poisoning) follows in a by no means negligible number of cases. The causation of this sequel

is unknown. There are, therefore, no precautions that intelligently be taken against it. For minor operations use of chloroform should cease, since its place can be taken by nitrous oxide and other agents. A previous condition suffering or anxiety or a prolongation of the stage of excitement renders a subject liable to collapse with a small dose. Risks of this sort are far greater with chloroform than with ether and greater with ether than with nitrous oxide. As they cannot be foreseen they cannot be avoided, except by replacing a dangerous anaesthetic by a safe one."

It is more accurate to say that chloroform *does* rather than *can* damage the liver, nor does ether *per se* cause pneumonia: the examples cited illustrate the abuse, not the use, of ether. When the contents of the G.P.'s waistcoat pocket are deemed inadequate to cope with some anaesthetic problem in a private house or nursing home, the expert does not find the transport of his apparatus an insuperable difficulty.—I am, etc.,

Aylesbury.

LOFTUS DALE.

### Trilene

SIR.—As manufacturers of trilene, I.C. (Pharmaceutical Ltd.) has been concerned about reports of toxic manifestation following the use of trilene as a general anaesthetic in a closed circuit with soda lime. Consequently upon suggestions made to us by Dr. H. E. Cox, Dr. Langton Hewer, and Dr. J. B. Firt that trilene underwent decomposition in the closed circuit with soda lime, we initiated investigations to determine this point. The results of these investigations were to have been the subject of a paper by us, but in view of the papers published in the *Journal* of March 4 by (1) Dr. J. H. Humphrey and Dr. Margaret McClelland and (2) Dr. S. Carden, our intended publication is not called for, as our investigations confirm the fact that dichloroacetylene is liable to be formed when trilene is used in a closed circuit with soda lime. A warning notice to this effect is now printed on all trilene packages, etc.—I am, etc.,

C. M. SCOTT,

I.C. (Pharmaceuticals) Ltd., Manchester. Director of Medical Research.

### Eye Signs of Anaesthesia

SIR.—Books on anaesthesia discuss the various signs of anaesthesia, but give comparatively small space to the eye signs which, in my opinion, are as valuable as other phenomena to assist in determining the plane of clinical anaesthesia. The late Mr. Herbert Charles of the Middlesex Hospital taught his anaesthetic clerks certain eye signs which are not generally known, at least by the younger postgraduate.

In consciousness the emmetropic subject, looking straight ahead into the distance, is seen to have the pupils "central and parallel." The pupil is midway between the palpebral fissure, and the rays of light are parallel on entering each pupil. This position of the eyes occurs at the beginning of inhalation anaesthesia, although the pupillary diameter may be altered according to the premedication. The size of the pupils need not be discussed here, as this is dealt with in all textbooks on the subject.

At the end of the first stage (Guedel's classification) the eyes, still parallel, begin to rotate downwards, and still more so during the second stage. This state is well seen in nitrous oxide, vinyl ether, and ethyl chloride inhalations. Towards the end of the second stage the eyes, still parallel, deviate to one side or the other. Occasionally coarse oscillations are noticed, but are too inconstant to be of any clinical value. The next well-marked phenomena occur in the first plane of the third stage. Here the eyes become markedly divergent, with the pupils usually above the middle line. This position is complete at the end of the first plane, with the pupils becoming centralized. As the depth of anaesthesia increases the angle of divergence becomes lessened, until the pupils are once again central and parallel. From here the position occurring in the early third stage remains unaltered, however much the depth is increased. As the stages of anaesthesia are reversed, so are the eye signs.

It will be seen, therefore, that these ocular movements form an accurate guide to the depth of anaesthesia.—I am, etc.,

London, W.3.

E. V. SLAUGHTER.

### Benzene Poisoning

SIR.—I have read the article by Drs. Hamilton-Paterson and Browning (March 11, p. 349). The writers seem to think there is no very satisfactory clinical method of detecting early cases. During the last war and for some years afterwards I examined large numbers of men. Early cases of poisoning were readily

detected by the one definite sign—viz., bleeding from the gums. I pointed this out in an article which I contributed to one of the medical journals at the time. Some of these men died, and at the necropsy haemorrhages into various organs were found. I am therefore of opinion that haemorrhage of any kind is always to be regarded as a danger signal in persons exposed to the risks of benzene poisoning.—I am, etc.

Edinburgh.

JAMES BURNIE

### Culturing Meningococci

SIR.—The article on meningococcal jaundice by Dr. C. Crawford (March 4, p. 325) interested me very much, and I wonder how the blood cultures were done. Two years ago, while I was resident in the City Hospital, Little Bromwich, Birmingham, we had two cases of suspected meningococcal septicaemia, and on the suggestion of Dr. Kerr I inoculated a blood agar plate, which was previously warmed in the incubator to 37° C., with a few drops of blood directly from the syringe, and in both cases we grew pure cultures of meningococci in 24 hours. Incidentally, neither of these two cases developed meningeal symptoms.

I think it would be worth while to try this method, as it seems to give very quick results.—I am, etc.,

Isleworth

E. LEIBOWICZ.

### Exomphalos

SIR.—I have read with interest the recent correspondence on this subject, and would wish to endorse the remarks of Prof. Lambert Rogers and Mr. Leonard Leys on the advisability of early operation for complete exomphalos. During 1943 three cases of exomphalos came under my care—two partial and one complete. The first infant, operated on within 5 hours of birth, had caecum, ascending colon, and ileum in the sac. Reduction of the contents was comparatively easy, recovery was uneventful, and six months later the child was thriving. The second child was admitted 72 hours after birth, the sac ruptured and infection was present. It contained the caecum, appendix, and lower ileum, and a vessel running from the mesentery to the apex of the sac had to be ligated. This infant also made a completely uneventful recovery and was fit and well when seen two months later. The third case was one of complete exomphalos and the child was operated on within three hours of birth. The sac contained the liver, stomach, and spleen as well as the caecum, ascending colon, and small intestine. Following Prof. Rogers's advice, I found that reduction of the liver was simplified by reducing the intestines first. This infant survived operation and lived for six months, only to succumb to an attack of acute gastro-enteritis. Where the liver is absolutely irreducible it may be partially exteriorized by suturing it to the wound edges.

Judging from the few cases published it seems well worth while attempting a radical cure by operation in all cases of exomphalos. The results in the partial variety are always likely to be good, but statistics indicate that operation should by no means be deferred in the complete type. To be successful the operation must be done within six hours of birth, and without operation the mortality is 100%.—I am, etc.,

Burnley.

E. W. THOMAS.

### Health Journal for the Layman

SIR.—I am not in agreement with Dr. J. Parness (Feb. 19, p. 270). The hypochondriacal magazines of the pseudo-scientific press will always flourish like the proverbial bay tree because they reflect a distinct (though pathological) attitude of mind. Apart from providing an income of sorts to the hack journalist, they afford an outlet for the morbid imagery of those who make a cult of ill-health. Like the platforms in Hyde Park or the letters of mental patients they serve a useful purpose in allowing an escape from repression. The healthy-minded public are, I believe, already sufficiently catered for. There is the "Radio Doctor." Most of the daily and Sunday newspapers feature occasional health and psychological articles, which are, on the whole, fairly sound and sensible, written by sufficiently well qualified doctors with a flair for the popular appeal. The women's journals and magazines usually have a medical journalist (perhaps not so well qualified) on their outdoor staff. Many of the weeklies

and monthlies present brightly written health articles on topics of current interest.

Responsible editors of to-day are, for the most part, too intelligent and well informed to allow quasi- or pseudo-scientific journalism any rope. If this adequate health diet is to be supplemented at all there are interesting possibilities in the future of films and television. I feel sure that a "popular" health magazine on sensible lines would fall between two stools: neither the neurotics nor the healthy-minded people would subscribe, at any rate for long. Indeed, if they did, they might soon become neurotic. Those who dwell upon their own health tend to become ill, or imagine they are, which is very much the same thing. Broadly speaking, the less an individual thinks of the "workings" of his own body and of his "feelings," the better he is. Now, I would like to know how the ordinarily suggestible person can subscribe to some presumably thoughtful health magazine, diligently reading through it, without giving some thought to the contents and their application to himself.

A quick perusal of an article in a newspaper, a brief instructive talk over the wireless (which you can turn on and off as you like), a film on some aspect of preventive medicine—these may be all right; but when you start bringing attractively dished-up health to the study or bedside for uncritical interpretation, that is the day hypochondriasis may be born. Moreover, a suitable editor for such a magazine will not be found growing on every gooseberry bush. Presumably he would need to be some well-qualified medical-man-cum-journalist with a mission. Not the least use that lay journalist with health interests; not the least use some medical grammarian inspired by academic textbooks; not the least use some exclusive body of experts who read this and review that, and who have to consult one another before making a move! With all due respect to certain eminent medical periodicals, that is not the sort of thing we want. And what about the contributors? From where are they to be drawn?—I am, etc.,

Exminster.

JOHN W. FISHER.

### Sulphaguanidine in Treatment of Flexner Dysentery

SIR.—Dr. H. G. Smith (Feb. 26, p. 287) has reported on toxic skin manifestations in almost 50% of his 44 cases treated with sulphaguanidine. His observations have struck me, inasmuch as Capt. A. E. Brewer (*Journal*, Jan. 9, 1943, p. 36) saw toxic symptoms in only 4% of his 51 chronic and in none of his 26 acute cases, although his dosage was in a number of cases not less than 142 g. given by Dr. Smith.

I do not wish to discuss the possible reasons for this discrepancy, but I should like to state that I saw no toxic skin manifestations among 26 cases of Flexner Z last autumn. The reason for it is, I think, that I gave not more than 12, 10, 6, 6, 6 g., or, in other words, about 40 g. were sufficient in all cases, except the one that relapsed, for the complete disappearance of the clinical symptoms and for six successive bacteriological negative findings. In this connexion I may state that I gave 150 mg. ascorbic acid a day from the onset until the clinical symptoms permitted minced vegetables, mashed potatoes, milk, etc., to be given.—I am, etc.,

Prestwich.

PAUL L. WEILL, M.D. (Tuebingen).

### Doctor and Patient

SIR.—In spite of adverse criticism Dr. Barlow's, of course, quite right; and those who, from some Olympian eminence, write editorial homilies directed at their colleagues in general practice should first try and get some first-hand experience of the intense frustration which conscientious doctors have been experiencing during the war years. This will not be acquired by doing a holiday locum for some general practitioner, but will need four years of wartime conditions. One detects the crack of a whip from higher up in this annotation, and in your editorial of some months ago where you castigated G.P.s for issuing certificates without examination, as if (as others have pointed out since) symptoms were not often more conclusive than physical signs.

It is this lack of *esprit de corps* and allegiance to one's own in all ranks of medical men and women which has always made the thoughtful doctor despair of his own profession.

With the best will in the world, how can a doctor with a 95% contract practice consistently refuse to give a certificate for, say, lumbago (that first and last refuge of a scoundrel), when he knows very well that someone else will if he doesn't? And is not this perpetual kicking against the pricks of the honest doctor the best argument for a State-controlled medical service, where his masters may be counted on the fingers of one hand, instead of being directly proportional to the number on his panel list?

One knows that the war effort is paramount, and that nothing should stand in its way, but it will be a bad day when the general practitioner loses his humanitarianism.

After all, even in wartime, one's patients are not all malingerers, and medical science, boast as it may, cannot measure that indefinable weariness, both mental and physical, which many are now experiencing.—I am, etc.,

HOVE.

G. L. DAVIES.

SIR.—It is a relief to know that the truth about the vexed question of what is wrong (as distinct from right) has, under divine providence, been declared to Dr. Frederic Sanders (March 4, p. 341). I had not pictured myself or my neighbours as rooting after the "nimble shilling" like a hog after acorns. But which of us knows himself?

However, I would not have further trespassed on your space and patience if I were not convinced that beyond the realm of abuse there is here an issue of major consequence. The doctor-patient relationship depends on mutual confidence. The obligation to avoid absenteeism is primarily the patient's. Most patients meet their obligations. With the absentee we are discussing default upon this obligation. Here the problem begins with the diagnosis of default. Since subjective evidence from the patient is a large part of many diagnoses in routine work, are we to say that the doctor shall accept it when he gives a certificate and reject it when he refuses one?

Even if a doctor were able to judge default with accuracy is it necessarily effective to drive a reluctant and resentful patient back to his work? Since in practice the refusal of certificates in the interests of the war effort commonly implies the herding back of the debilitated with the defaulter, is not the end in view likely to be defeated by the measures taken?

• There is now so much pressure on the doctor to make a moral or a social judgment where the situation demands a diagnostic or a therapeutic judgment that in my view it is dangerous for the practitioner to allow outside considerations to influence his obligations to his patient. This is particularly true at present when the State, with new duties and new coercions, hovers darkly on the medical horizon. Now more than ever I would say the purist's attitude is right. The doctor's obligation is to his patient and to him only. The only rider I would add is that which justifies the public control of infection. I am, etc.,

OXFORD

K. E. BARLOW.

### Tonsillectomy in Children

SIR.—In the recent correspondence in the *Journal* on this subject too much importance has, I feel, been given to the removal of the faucial tonsils, with the consequent overshadowing of what is, in my opinion, by far the more important part of the combined operation—that is, the efficient removal of adenoids.

Undoubtedly, recurring attacks of sore throat and cervical adenitis are the symptoms for which the majority of such patients are referred to the laryngologist, while such symptoms as transient attacks of earache, deafness, and nasal catarrh are only too frequently waived aside or treated lightly, since on examination of the throat the faucial tonsils appear healthy. While admitting that in most cases of adenoids there is usually evidence of tonsillar hypertrophy, this is not invariably so, and herein lies the reason why so many of these cases are missed. I would stress this point, for such aural symptoms are of the utmost importance as being the precursors of recurrent attacks of otitis media, and the direct cause in many cases of chronic middle-ear disease with its attendant distress. In all such cases, therefore, an examination of the nasopharynx should be undertaken, and in the vast majority adenoids are found to be present.

Mr. Layton makes an important point when he says that the physiological function of the palate and fauces is frequently disturbed by the fibrosis consequent upon the removal of the faucial tonsils, and I submit that, in a large number of cases, as much benefit is to be obtained by the efficient use of the adenoid curette by itself as by subjecting the patient to the more fashionable operation of combined removal of both adenoids and tonsils.—I am, etc.,

Dartford.

MORTON G. MARKS.

### Consultant and Specialist Services

SIR.—May I, on behalf of my fellow specialists, be permitted to thank Mr. Hamilton Bailey for his courageous letter of Feb. 19 (p. 270). While admitting the great experience that membership of the staff of a teaching hospital confers, may I direct attention to the necessarily small number of teaching hospitals throughout the country? Is it, perhaps, suggested that all of us engaged in specialized practice and not on the staff of a teaching hospital should, by some manoeuvre, be admitted to the "charmed circle"? Perhaps something like Hitler's "honorary Aryans" is intended? If so: it would be in keeping with the "oyster-like" secrecy of the "Herrenvolk."

If a register we must have, why not let us all know why, where, when, and how. Perhaps one of those in the know can enlighten us.—I am, etc.,

London, W.I.

DAVID HALER.

## Obituary

H. G. TURNEY, D.M., F.R.C.P., F.R.C.S.

We regret to announce the death on Feb. 26 at his house in Park Square West, London, N.W., of Dr. Horace George Turney, O.B.E., consulting physician to St. Thomas's Hospital.

Born in 1861, he began his medical education at Trinity College, Oxford, and continued it in London at St. Thomas's Hospital, taking his first medical degrees in 1888. Having held house appointments at St. Thomas's he proceeded to the M.Ch. degree at Oxford in 1890 and to the D.M. in 1897, by which time he had taken the M.R.C.P. diploma and also the F.R.C.S. He was elected F.R.C.P. in 1898. It was while holding the post of resident assistant physician at St. Thomas's that his bent for clinical medicine showed itself unmistakably: in due course he was promoted to the honorary staff, and after many years of faithful service to the hospital and its medical school he retired and was elected consulting physician. At the Royal College of Physicians he served on the Council in 1915-17 and as Censor in the years 1921, 1922, and 1924. He examined for the English Conjoint Board in 1916-20, and had been external examiner in medicine for the University of Liverpool. He was also at one time medical referee to the Treasury. For his services during the last war, with the rank of captain, R.A.M.C.(T.), he was awarded the O.B.E. (Military) in December, 1919.

Dr. Turney's interest in disease of the nervous system, while practising as a general physician, was recognized by his election as president of the Neurological Section of the Royal Society of Medicine and by the invitation given him to contribute the article on the trophoneuroses for *Allbutt's System of Medicine*. One of his sons, Dr. Horace Ferguson Turney, has practised for some years in London.

We are indebted to Sir FARQUHAR BUZZARD for the following appreciation:

My memory of H. G. Turney, who has died recently at the age of 83, goes back 50 years to the time when I became a student at St. Thomas's Hospital and found him and H. P. Hawkins the two youngest physicians on the teaching staff. From that day to this one has thought of him almost always in that connexion for the reason that he devoted the greater part of his life and energies to the hospital and never took a very prominent part in outside professional activities. True, he was for three years a Censor of the Royal College of Physicians and held the presidency of the Neurological Section of the Royal Society of Medicine, but he was not a very regular attendant at the meetings of medical societies.

made no great contributions to medical literature, and was little known to the general public as a consultant. He belonged in fact to a group of teaching consultants in the large medical schools of London whose chief interests lay in their hospital duties and responsibilities. And in this direction his services—to patients, students, and nurses—were invaluable and warmly appreciated. Turney collected many diplomas in his younger days, both medical and surgical, and was unusually well equipped as a general physician with a strong leaning towards neurology. His mind was that of a scholar rather than of a craftsman; widely read and with a remarkably retentive memory, he had a profound knowledge of medical literature. Unlike that of his colleague Seymour Sharkey, whose successful coaching for examination purposes was very popular among the students, Turney's teaching was best appreciated by a select few who could always rely on him for good advice in regard to their reading and scientific studies. To be his house-physician was an experience of real educational value, as he never spared himself in giving help and encouragement both to his younger colleagues and to his patients.

A retiring, unselfish, generous, and learned physician, whom many generations of St. Thomas's men will look back upon with gratitude, admiration, and affection.

#### SIR HENRY MAUDSLEY, K.C.M.G., M.D., F.R.C.P.

News has reached this country from Australia of the death on March 5 in the Royal Melbourne Hospital of Sir Henry Carr Maudsley, consulting physician to that hospital and to St. Vincent's Hospital, and formerly lecturer on medicine and clinical medicine in the University of Melbourne.

Born in Yorkshire on April 25, 1859, the eldest son of Thomas Maudsley of Stainforth, Settle, he was educated at University College, London, graduated M.B., B.S.Lond. in 1881, and obtained the M.D. two years later after serving as resident medical officer at University College Hospital. He took the M.R.C.P. in 1884 and was elected F.R.C.P. in 1901. Making his home in Melbourne he was for some years physician and pathologist to the Alfred Hospital, and also physician to St. Vincent's Hospital. For his services during the last war he was mentioned in despatches, created C.M.G. in 1916, and three years later K.C.M.G. and C.B.E. Sir Henry Maudsley joined the British Medical Association in 1907, and at the Annual Meeting in Melbourne in September, 1935, he held office as vice-president of the Section of Neurology and Psychological Medicine.

Dr. J. E. M. WIGLEY writes: As an old student of Sir Henry Maudsley's, of whose recent death I have just read, I would like to take this opportunity of paying a tribute to his memory. His ward rounds at the Melbourne Hospital have left a lasting impression of his sound, kindly, and sympathetic dealing with his patients, while his teaching was always essentially clinical, laying great stress on the funds of knowledge which could be obtained from careful observation. The outbreak of the last war prevented my applying for the position of his house-physician, a post always much sought after. He will always remain in my memory as a fine example of the term applied to a great leader of medicine—"a beloved physician."

#### G. L. EASTES, M.B., B.Sc.

George Leslie Eastes, who died at Gerrards Cross on March 4 after a long illness, was born in London on Dec. 16, 1870. The second son of George Eastes, M.B., F.R.C.S., who for many years practised in Gloucester Terrace, he was educated at Marlborough, proceeding to London University and Guy's Hospital. He took his B.Sc. with honours in physiology in 1892 and qualified M.R.C.S., L.R.C.P. in 1894, obtaining the M.B., in which he won honours in medicine and forensic medicine, in 1895. After holding the post of house-surgeon at the Sheffield Royal Hospital he became interested in clinical pathology, which was his life's work, and was appointed director of the Clinical Research Association. In 1901 he founded the Laboratories of Pathology and Public Health, which he converted into a private company in 1938 with the object of assisting medical charities, holding the position of chairman until failing health compelled him to abandon all professional activities. His interests tended more towards the public health than the clinical branches of pathology, and

he was the author of several publications on bacteriological subjects. During the last war he served in the R.A.M.C. in the Middle East and held the rank of captain, being mentioned in despatches. Dr. Eastes joined the B.M.A. in 1895, and was secretary of the Section of Pathology at the Annual Meeting held that year, and vice-president in 1933. He leaves a brother and sister.

H. S. W. writes: Clinical pathology loses in G. L. Eastes a man who perhaps did more than any other to make the medical profession "pathology minded." After a short period as director of the Clinical Research Association and pathologist to Great Ormond Street Hospital he founded the Laboratories of Pathology and Public Health, bringing to the medical profession a pathological service previously unobtainable. His work was characterized by the most careful attention to detail, which, with his great experience, caused his opinion to be widely sought. As a colleague he was ready to advise and assist his juniors in any difficulties that arose in the course of their work, and his advice was invariably sound. Although of late years he had ceased to take an active part in the working of the laboratory, he was always keenly interested in its work. His hobby was archaeology, and he wrote a monograph on Saxon remains in English churches.

We regret to announce that Dr. JAMES ORR, director of the James Mackenzie Institute for Clinical Research, died at St. Andrews on March 9. Born in 1876 at Hawick he was a son of the late Prof. James Orr, D.D., of Edinburgh, and was educated at Watson's College and Edinburgh University, graduating M.B., Ch.B. in 1899. He was for some years resident medical officer to the City Parochial Hospital, Craiglockhart, after a house-surgeoncy at the Dundee Royal Infirmary. During the last war he served in Egypt with a temporary commission in the R.A.M.C. Dr. Orr was author with Sir James Mackenzie of the well-known book *Principles of Diagnosis and Treatment of Heart Affections*, which went into a third edition in 1926, and his long connexion with the James Mackenzie Institute began when he joined the staff as physician. He obtained the M.R.C.P.Ed. in 1927 and was president of the Fife Branch of the B.M.A. in 1931-2.

Dr. ERNEST J. PEILL, who has died in Edinburgh as the result of a motor accident, was a remarkable man. He did outstanding work in China as a medical missionary for 27 years. Born in Madagascar the son of a missionary, he and his two brothers, Arthur and Sidney Peill, graduated in medicine at Edinburgh University. They all three gave themselves to missionary work in North China. Later he came home and took the F.R.C.S.Ed., devoting himself chiefly to surgical work. In 1901 he was appointed by the London Missionary Society to the charge of the Siao Chang Hospital, to which he gave much distinguished service. In 1911 he went to Peking on appointment as professor of surgery in Peking Union Medical College—the precursor of the present Rockefeller College, where he raised the tuition of surgery to a high standard. During the last war Dr. Peill volunteered for service with the Chinese Labour Corps, as he had a fluent knowledge of the language, and was sent to the Chinese General Hospital (2,400 beds) at Noyelles in France. There he was appointed officer-in-charge of the surgical division, and in this capacity did splendid work. He retired from China in 1928, and was made medical superintendent of Quarrier's Homes at Bridge of Weir, where he successfully specialized in the surgical treatment of tuberculosis. He was, however, unable to continue in this work because of ill-health. During the present war he became a leading member of medical recruiting boards in Edinburgh. He had a calm and sympathetic temperament that made him greatly beloved by all with whom he came in contact, especially the Chinese, among whom he spent the best years of his life, and to whom his courteous, philosophic, and courageous character greatly appealed. Though of a retiring nature, he had a great many friends, and was much respected and loved by all who knew him.—G. D. G.

Dr. ALASTAIR MACGREGOR, well known for his work on physiotherapy, died in London on March 13. He was born at Inverness on Sept. 1, 1864, son of the Rev. Alex MacGregor, M.A., and was educated at Inverness Academy, Edinburgh Academy, and Edinburgh University, graduating M.B., C.M. in 1885 and proceeding M.D. in 1905. Coming to London he became casualty officer and clinical assistant in the electrical department of the West London Hospital and afterwards served for 17 years as chief assistant in the electrical department of St. Bartholomew's Hospital. On the outbreak of the last war he joined a medical formation attached to the 10th French Army and later served in the electrical department of the British Red Cross Hospital at Netley, and at the King George Hospital and the Paddington Military Hospital. He was later appointed

never been consulted in the framing of this scheme. A body called the Representative Committee of the medical profession had met the Minister of Health in March, 1943, and were told what had been decided. In July, 1943, the chairman of one of the larger committees of the B.M.A. authorized a statement that negotiations must be based on acceptance of a Cabinet decision that a single unified health service covering all the population would be instituted, and that local administration would be under local authorities responsible to a Minister. At a meeting in London the Minister informed the Representative Committee that it was proposed to secure control of the medical profession "in order to keep a firm hand on the issue of certificates." The proposals in the White Paper followed the decision of the Cabinet as announced. It would be impossible to work a scheme if those operating it intensely resented the conditions imposed on them.

Dr. SUMMERSKILL intervened to say that Sir Ernest represented the views of a small section of the profession. Dr. RUSSELL THOMAS: "Of the vast majority."

Sir ERNEST said that less than 10% of those who would be asked to work this scheme favoured it. The total on the *Medical Register* was 70,000, of whom 50,000 were in practice. About half the general practitioners were serving in this country and half abroad. Of doctors questioned in cities and large areas of this country 90 to 95% were against proposals involving lay control of the profession. The Representative Body of the B.M.A. at a meeting in September, 1943, rejected, by 200 to 10, the proposed reduction of the profession to a salaried medical service. A more recent questionnaire sent to 30,000 practitioners in active practice in this country resulted in 70% opposition to lay control by a central authority. Dr. MORGAN said the questionnaire dealt not with policy or principles but with details of the scheme.

Continuing, Sir ERNEST said the B.M.A. proposed to consult its members who were serving overseas. It would be difficult for any serving officer to answer its questions with due consideration. The Health Centre had attractive features, but was it possible for there to be a free choice of doctors after the institution of the Health Centre? The prospect of a number of specialists in connexion with these centres was illusory. The prospect of any worth-while private practice surviving was not hopeful. At present, under Defence Regulations, doctors were forbidden to transfer their services. Was that type of direction going to be perpetuated? In recent years, by development of contributory schemes, the voluntary hospital system had become a widely appreciated co-operative system of medical service. The proportion of staff to patients was much larger at the voluntary hospital, the comparison being about 10% at the voluntary hospital and 1% at the public hospital. Voluntary hospitals were centres of research because consultants gave their time. Under what conditions would these consultants work if the Government scheme were adopted? General practitioners would be under the strict rule of the Central Medical Board.

#### *B.M.A.'s "Disagreement Only in Detail"*

Dr. HADEN GUEST said he did not claim to represent the medical profession and denied Sir Ernest Graham-Little's claim to represent any large part of it. Sir Ernest did not represent the views of the B.M.A. Most medical persons would agree there could be as free choice of doctors in a Health Centre as there was elsewhere. The White Paper was a reasonable basis for discussion. He hoped the Government would let the House know whether private practices which were set up in the future would be saleable or not. The period during which that commercial element in practice should continue should be as limited as possible. Ultimately every doctor, nursing service, and hospital should be a combination of service to the State with the retention of voluntary initiative in certain ways. If the voluntary hospitals stood out from the scheme their influence would dwindle. He was convinced that the leaders of the London teaching hospitals would throw their authority into a unified hospital system. The B.M.A. only disagreed with the White Paper in matters of detail.

Mr. CRAIK HENDERSON thought there should have been longer after the publication of the White Paper for the views of the medical profession, the voluntary hospitals, and the public to be ascertained. It was unjust to ask the voluntary hospitals to come under a joint authority where all the power would be given to the body owning the alternative form of hospital service. Voluntary hospitals should have the right to nominate their own representatives to the Central Health Services Council. A central hospital advisory committee containing representatives of the voluntary and State hospitals should be set up to consult with the Minister. A local joint hospital committee for each area should also contain representatives of voluntary and State hospitals. If necessary there could be a neutral chairman. Legislation should lay down the sum to be paid by local authorities in respect of the number of beds in voluntary

hospitals. There should be a Hospitals Grants Committee analogous to the University Grants Committee.

Mr. ALEXANDER WALKDEN, speaking on behalf of the Labour Party and the T.U.C., said he had been asked to congratulate Mr. Willink on the White Paper, which would be the basis of a Government Bill. The new plan would be specially welcomed by the women of the country. Young doctors and medical students whom he had seen welcomed the idea of full employment in Health Centres.

Dr. HOWITT welcomed the White Paper and said the great majority of the medical profession would do so. It showed the contributory scheme was dead, but the voluntary hospitals were not going to be shut. When replies were received in July to the medical questionnaire they would show that the vast majority of the medical profession did not want a great increase in the salaried services. To run this National Health Service satisfactorily there must be a 50% increase of doctors, but the White Paper as it stood would not attract the best people into the profession. The Minister must make the profession attractive and leave ample scope for initiative, hard work, and independence.

Dr. MORGAN declared that the White Paper was a step in the right direction, but it did not propose a comprehensive national health service. The stress was on the medical side at every stage; public health and social medicine had been left out. Not a word was put down about a preventive policy in industrial medicine. When doctors looked at existing medical services they had grounds for their misgivings about bureaucrats. The Colonial Medical Service was one of the worst in the world.

Mr. STOREY said it was hard to refrain from the conclusion that those who framed the White Paper proposals shaped the scheme so that the voluntary hospitals could continue in business only if prepared to provide a service at less than cost, so that, at no distant date, it would be possible to acquire at scrap prices the voluntary hospitals, their buildings and equipment, and to build them into a State service. Sir JOHN GRAHAM KERR said the prospect of mounting step by step in a safe, organized profession would be less attractive to brilliant young men than the present system in the medical profession. Mr. DOUGLAS remarked that nothing in the White Paper was actively directed to dealing with the cases of disorder which were not recognized as illness and laid the foundations of permanent disease.

The debate was adjourned.

#### *Debate Renewed*

Miss HORSBRUGH on March 17 reopened the debate. She said Dr. Howitt had referred to the supply of doctors. The Government had looked into that. There was at present about one doctor to 2,000 of population, but these doctors were not evenly distributed. There were far too few consultants and specialists. Wartime admissions to the medical schools had been at the rate of 2,300 a year. The Minister would be responsible for the Central Medical Board, and he was also responsible to Parliament. There had never been any policy of direction for doctors. The doctor could set up a private practice wherever he liked. There was no control of private practice. He could, if accepted, do full-time public service. He could do part-time public and part-time private practice. But if there were a shortage of doctors in an area to which a young doctor wanted to go to do part-time public and part-time private practice he might be told that he must do full-time public practice there, but that there were many other opportunities in the country and he could choose one of them. Members had asked if there were to be no Health Centres where there were beds. The Government wanted experiments with different types of Health Centres.

A great deal of the previous discussion had turned on hospitals. The Emergency Medical Service had enabled the Government to bring the hospitals, both municipal and voluntary, into a common service, with interhospital transport, and specialists at the different hospitals. Each hospital had kept its identity. Similarly the Government wished to bring all the hospitals of the country into the new scheme. Parliament was now making the contributory scheme for voluntary hospitals a universal and compulsory one. She could not agree that the money should be paid to an individual hospital, but she believed that gifts from grateful patients would continue. The hospitals, if they wished, could still have paying beds. She believed that the Government was helping the voluntary hospital to continue as an independent unit. The Government must have further discussions on how payment should be made to the voluntary hospitals, and might include a pooling scheme. There would be Government inspection of both municipal and voluntary hospitals to see a proper standard was maintained. All types of hospitals would contract to do particular work, for which they would receive payment in addition to flat-rate payment. The hospital could accept or refuse the contract. If there were

not enough beds in an area the joint board must supply them, if necessary by a new hospital. She thought the hospitals would be pleased to come into the plan. She believed that young men and women would have far greater opportunities in medicine. They would not be hampered by patients' inability to pay. Schemes of research, training, and teaching would give the best opportunities.

Mr. GREENWOOD said a bigger personnel would be required in the profession and provision for medical teaching must be extended. Existing teaching hospitals would be inadequate. He would like to see more prominence given to mental treatment. The medical profession existed for the public good, and doctors could not be the final factor in determining the future of the scheme. Nor could the voluntary hospitals. The Labour Party accepted the scheme as a substantial instalment in a public health service. Mr. MESSER said it would be better for the general practitioner who did not want to come into the scheme to keep out of it. He would not refuse that practitioner the right of following up his patients who came into hospital.

#### *End of Private Practice*

Sir HENRY MORRIS-JONES said he would have preferred the scheme to be confined to those who needed it. If the scheme succeeded there would be a practical abolition of private practice. If private practice still flourished five years after the introduction of the scheme that would mean that the scheme was a failure. Dr. SUMMERSKILL called the scheme a coalition compromise. It was planned to cure disease rather than to prevent it. The scheme would accentuate social distinctions in the treatment of disease. When they gave the doctor a salary they got the best out of him. To allow publicly paid doctors to take fees was a kind of thing not allowed in the Department of Whitehall and should not be allowed in the medical profession. The Government hoped to starve the voluntary hospitals into submission, but the process might take a long time. Scottish members continued the debate. Major LLOYD asked what would be the position of the mental hospitals in Scotland of a voluntary character, seven of which had Royal Charters. Their beds were about a quarter of all the sick-beds in Scotland. Were they to be taken into full partnership by the joint boards or the regional councils?

Mr. TOM JOHNSTON, winding up the debate, said the proposals had been agreed to by all sections of the Government. The Government proposed no compulsion on doctors to come into the public service. The new service could not be put into operation all at one time. It was proposed to discuss the whole question of payment, including options, with the medical profession. Whatever system was adopted the number of patients which a doctor could undertake must be limited. But if the doctor stayed out he could take any number of patients. He thought the selling of practices a degrading system. It would be discussed with the profession. There was no question of stopping all private practice.

Of voluntary hospitals, one-quarter were run in a pre-war year with a deficit. Flag days for hospitals were not a commendable way for a great service to finance itself. There must be a better way. Scotland had seven large base hospitals, with about 7,000 beds, for war emergency services. These would make a great addition to the hospital service which the Government hoped to have in the near future by agreement of all concerned. Co-operation had been secured in one or two areas. In Aberdeenshire and Kincardineshire, and in Gloucestershire, there were arrangements for transfer of convalescent patients from key hospitals to other hospitals. There was no Government antagonism to voluntary hospitals. The Government invited them, as autonomous organizations, to co-operate in making the new health service a success. They appeared willing to co-operate. The voluntary hospitals in Scotland had agreed for numbers of their waiting-list patients to be treated in the State hospitals. Some 26,000 patients from the waiting lists had been thus treated.

The House then carried the resolution moved by Mr. Willink.

#### *Nutrition and Infant Mortality in Scotland*

Opening a debate on March 8 about nutrition and infant mortality, Mr. TOM JOHNSTON said the total consumption of liquid milk had risen 34% since 1939. In Scotland 67% of the whole school population received milk at school; in England and Wales 78% of the children at school. Sir John Orr had said a survey of working-class families in industrial towns in Scotland had shown that there was a definite improvement in the health value of their diets, the average intake of some of the important vitamins and minerals being over 20% higher than in the pre-war years. Over a fifth of the children attending school were given a midday nutritious meal in Scotland. In England the figure was 29%. Vegetable consumption had remarkably increased. In Glasgow in 1943 boys entering

school life were 0.40 in. taller and 1½ lb. heavier than boys who entered school life in the pre-war quinquennium. Girls increased 0.28 in. in height and nearly 1 lb. in weight. Tuberculosis, however, increased because of deterioration in the housing conditions and not nutrition.

Infant mortality in Scotland was decreasing. Last year it was 65 per 1,000 births, the lowest in the annals, but maintained a ratio 30 to 40% higher than in England. The report from the Scientific Advisory Committee on this subject had aroused widespread interest. Despite criticism that it was unduly weighted in favour of nutritional aspects of the problem, it was a report of great competence. Bad housing, while a high contributory factor to infant mortality, was by no means the sole one. He would like to draw the attention of local authorities in Scotland to the fact that in January of this year the intake of welfare foods for mothers and children was still lower than the corresponding figures for England and Wales 7% worse in cod-liver oil, 20% worse in vitamin A and D tablets, and 18% worse in the intake of orange juice. That matter should be corrected by the medical officers of health concerned.

#### *Deaths from Infections: Special Inquiry*

Scotland had more maternity hospital beds to births than England, and more births in institutions. During the war also the number of hospital beds in Scotland had increased by 50% to 2,260. In Glasgow 55% of births were in hospitals and nursing homes (40% in 1938), in Edinburgh between 60 and 70%, in Dundee 77%, in Aberdeen 75%. Increased use was being made of ante-natal clinics. In Glasgow last year about 77% of expectant mothers attended ante-natal clinics. About one-quarter of the total deaths in the first month of babyhood were due to infections. In a consecutive series of 25 post-mortem examinations of children dying during the first month in the Maternity Pavilion, Edinburgh Royal Infirmary, 27% of the deaths were judged to be due to infection. At one time there were similar outbreaks in English and American hospitals. He was inviting the Scientific Advisory Committee to pursue as a matter of urgency an inquiry into this aspect of the problem.

Mr. Johnston then summarized what his Department was doing upon the conclusions of the Orr report as follows: (1) They were asking for a detailed examination of why 25% of the deaths of newly born babies are caused by infections. (2) They were taking every step to prepare the way for a vast increase in sanitary and healthy housing accommodation. (3) The local authorities were doing their utmost to increase the intake of certain vitamin products by mothers and babies, to increase the number of qualified health visitors and house-helpers and the quality and use of the clinic services and the number of maternity beds. (4) The Central Council for Health Education would assist in every way possible to inculcate the advantages of high standards of personal hygiene and conduct.

Mr. BUCHANAN said the Government should proceed with housing now. Glasgow had a population of 1,000,000, half of whom had no baths and one-third of whom shared lavatory accommodation with other families. The reforms recommended by Mr. Johnston were not big enough. Mrs. TATE said the general level of well-being of the people was not high. They lost their teeth at an early age. A vast proportion were tired and listless, pallid, and not in an adequate physical condition. In view of the housing conditions she marvelled that women had courage to try to cook. Fresh milk was often not drunk because of the lack of any place in which it could be stored without going bad. Why were large supplies of the few drugs available given to the vested interests which produced quack medicines? Did anyone test these medicines to see what the contents actually were?

#### *Estimated "Hard Core" of Infant Deaths*

Dr. RUSSELL THOMAS recalled the infant mortality figures for England, Wales, and Scotland. Those for Scotland were only exceeded in Europe by countries like Spain, Portugal, and Hungary. Bronchitis and bronchopneumonia accounted for the large number of deaths in children under 1 year and were frequently associated with other infectious diseases. To control this death rate mothers must be educated in the care of infants. Parliament must see that the nutrition of mothers before and after the birth of the child was maintained on a high level. If they could proceed with these health measures and with housing, the infant mortality from infection would be reduced to a very low level. He thought infant deaths from this cause could be reduced to 12 per 1,000. They would have to leave the figure of 6.1 per 1,000 as a hard core of congenital malformation. Infant deaths from congenital debility had been reduced in England and Wales from 15 per 1,000 in 1906-10 to 2.1 in 1937-40. In Scotland the figure had not gone down in the same way, and was 7.6 in 1937-40. It should be possible to reduce it to the English level. There had been an increase in mortality

due to injuries at birth: in Scotland the increase was from 1.3 to 3 and in England from 1 to 2.5. The ordinary confinement was now normally attended by the district nurse, and the doctor was only called to the difficult ones. If he lost the experience which he would get from simple confinements a lack of skill might possibly be developing in the practitioners of the country. Dr. Thomas put the hard core of infantile mortality from inevitable accidents at birth to about 2. In death resulting from premature birth there had been little improvement from 1906 to 1940. He suggested that 14.4 was the figure beyond which we could not go in saving life in premature birth until knowledge had increased. Over the whole field he suggested that 36.5 per 1,000 should be the hard core of deaths in the first year of life in England and Wales, comparing with the New Zealand figure of 32.7. The difference in these figures was accounted for by the greater amount of respiratory disease in this country.

Dr. EDITH SUMMERSKILL contended that all other types of mortality apart from cases of congenital malformation could be traced to poverty, bad housing, under-nourishment, and other such conditions. Few surveys had been made on the physical condition of the expectant mother, but when one was made of families divided into five groups by incomes the report was that only the highest groups approached the necessary standard in protein and iron and only the highest in calcium. The supply of vitamins A, B, and C was inadequate except in the highest group. The position became progressively worse towards the lowest income group. If this kind of thing was allowed to exist women would not be able to resist tuberculosis. Some infection was the cause of death in 25% of cases of infant mortality, and practically all the children were bottle-fed.

Major MARKHAM pointed out that two months ago Lord Woolton, in a speech to the Parliamentary Science Committee, gave that committee to understand that the national diet had been so reorganized that it was completely free of vitamin deficiency, and, in addition, other elements such as calcium and iron had been added to the daily diet. Immediately after that speech the Boyd Orr report was published, based on pre-war facts and figures, and had banged the old nutrition drum. What the House would have welcomed in the report was an up-to-date analysis of the causes of infant mortality. For that report to close the evidence at Sept. 3, 1939, was a crime against the mothers of Scotland and England. He regretted that no reference had been made to climate or to the control of temperature indoors, which caused a rise in infant mortality of 52 to 100% every winter.

Miss HORSBROUGH, replying to the debate, said the Ministry agreed that housing conditions in England and Wales, and above all in Scotland, were appalling and had got worse during the war. There was no labour and material for the building programme while the war was being fought. All that could be done was to see that after the war there was not the delay there was after 1918. Credit should be given to those who in these war years had worked hard—the health visitors, the nurses, etc. It was hardly fair to say the services were bad. The Government wished to see them better, but could be proud of the work that had been done. It was remarkable that in the last year in England 96.5% of the mothers who gave birth to children were visited in their homes within a week. Beds maternity homes and hospitals had been increased by 3,000.

1 England and Wales had in institutions accommodation for at least 50% of the mothers of the country. Mr. Johnston had given alarming figures on infection in hospital. To have a maternity home or hospital in any way overcrowded when there was not sufficient isolation or insufficient staff to make isolation good was more dangerous than to have children born at home. A draft circular was going out to local authorities on provisions which could be made in wartime to make premature births as normal and the death rate as low as possible. In this, hospitals were doing wonderful work, but what was needed was to see how prematurity could be prevented. Where attack had to be made was on the mortality during the first month after birth. In one place where neonatal mortality was high the Ministry was arranging an inquiry into the nutritional standard. Such inquiries had been made in many parts of the country and many hundreds of expectant mothers had been examined, but as yet the Ministry had found that the nutritional standard was not bad. It was disappointing that only 50% of the mothers and babies in England to whom fruit juice was available took it; only 25% took the cod-liver oil, and only 39% the vitamin tablets. The Advisory Committee of the Ministry had dealt with the subject of the premature baby and rickets, and a report on rickets would shortly be published by the British Paediatric Association. The investigation of rickets was reassuring, for it was one of the diseases which had been thought likely to increase in wartime.

## Universities and Colleges

### UNIVERSITY OF EDINBURGH

It is announced that Prof. P. S. Lelean, C.B., C.M.G., F.R.C.S., will retire at the end of this year from the Bruce and John Usher Chair of Public Health in the University of Edinburgh, which he has held since 1926. During his tenure of the professorship he has greatly widened the scope of the teaching in public health, introducing instruction in child welfare, hygiene at different periods of life, and the various social conditions that have a bearing on the health of the community; he has also increased the co-operation of the Medical Officer of Health for the city and his staff in connexion with the public health course. Prof. Lelean served, as a regular officer of the R.A.M.C., in the South African War, in India, and throughout the war of 1914-18. During his period of office as professor of hygiene in the Royal Army Medical College at Millbank he trained many officers, both regular and temporary, in military hygiene. He retired from the Corps in 1922 with the rank of brevet colonel.

### UNIVERSITY OF BIRMINGHAM

A course of six lectures on industrial medicine for industrial medical officers and others will be held at the Medical School, Hospitals Centre, Birmingham, 15, on the undermentioned dates; the lectures will take place at 4 p.m. in the Physiology Lecture Theatre: April 5 and 6, "Tuberculosis in Industry," by Dr. Halfiday Sutherland. April 12, "The Education of Doctors for Industry," and April 13, "The Prevention of Disease in Industry," by Dr. Donald Hunter; April 19 and 20, "Factory Hygiene: Assessment of Standards and Methods of Investigation," by Dr. Donald Stewart. The fee for the course is £1 1s., which is payable in advance to the Secretary of the University, Edmund Street, Birmingham. Nurses engaged in industry are invited to join the course at a fee of 5s.

### UNIVERSITY OF SHEFFIELD

A legacy of £1,000 bequeathed under the will of the late Emeritus Professor R. J. Pye-Smith, who held the chair of surgery in the university until his retirement in 1910, has now been received by the University of Sheffield.

The following candidates have been approved at the examination indicated:

M.B., Ch.B.—Parts II and III: JE. S. Machell, E. S. L. Allott, G. D. Banks, Margaret A. M. Howard, Helen N. Mellanby, N. A. Vincent.

<sup>1</sup> With second-class honours.

### UNIVERSITY OF DUBLIN

#### SCHOOL OF PHYSIC

The following candidates have been approved at the examination indicated:

M.B., B.Ch., B.A.O.—D. H. Draper, C. J. Dugdale, C. W. C. McCreery, M. W. Strench-O'Carroll, R. M. C. Tyner, I. H. R. Woodrow.

## The Services

Capt. (Acting Major) J. P. Fletcher, R.C.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in Italy.

The Shahinshah of Iran has conferred the Order of the Crown on the following officers in recognition of distinguished services in the cause of the Allies: Lieut.-Col. (temp. Col.) D. W. E. Burridge, R.A.M.C. (4th Class); Lieut.-Cols. E. S. S. Lucas and R. K. Tandon, I.M.S. (5th Class).

### CASUALTIES IN THE MEDICAL SERVICES

*Previously reported missing at sea, now presumed killed in action.*  
—Major R. A. Foucar, R.A.M.C.

*Reported missing, believed killed.*—Surg. Lieut. F. M. McRae, R.N.V.R.

*Died.*—Surg. Cmdr. A. W. Cocking, R.N.

### DEATHS IN THE SERVICES

Wing Cmdr. RICHARD STANLEY TOPHAM, who died suddenly on March 10, was born in July, 1890, and studied medicine at Leeds University. He qualified M.B., Ch.B. in 1915 and was commissioned in the R.A.M.C. in May, 1916. He served with the Army until 1918, when he was appointed to the Medical Branch of the Royal Air Force. He obtained the D.P.H.Camb. in 1920 and the D.M.R.E. in 1925. He was placed on the retired list at his own request in 1927, and held important radiological appointments at Chester. On the outbreak of the present war he returned to duty with the R.A.F., and early in 1940 was appointed senior medical officer with charge of the hospital at a large R.A.F. station in England.

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 4

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland

Figures of Births and Deaths, and of Deaths recorded under each infectious disease for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

\* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

## EPIDEMIOLOGICAL NOTES

## Discussion of Table

In England and Wales during the week there were rises in the notifications of measles by 191, acute pneumonia by 125, whooping-cough by 104, and scarlet fever by 49; cerebrospinal fever was down by 22 cases and dysentery by 16.

Whooping-cough was more prevalent in the south, Suffolk notifying 43 more cases than last week, Sussex 36, and London 23; the only drop of any size was in Yorks West Riding, where 30 fewer cases were reported. The increase in measles was due mainly to local outbreaks in a few areas. The counties with the largest increases were Lancashire with 119 more cases, mainly in the urban districts; Gloucestershire with 68 more (Stroud R.D. 54, East Dean R.D. 16); Northumberland with 66 more (Newcastle-upon-Tyne C.B. 32, Gosforth U.D. 37). A fall of 61 was recorded in Kent.

Dysentery notifications exceeded 200 for the fourth consecutive week. In London there was a rise from 14 to 33. The chief of the other centres of infection were Lancashire 32, Surrey 18, Essex 17.

There have been no new cases of smallpox, the total to date numbering 11.

In Scotland there were 22 more notifications of measles and 33 of acute primary pneumonia, but there were 51 fewer cases of whooping-cough and 36 fewer of scarlet fever. The notifications of dysentery rose by 3.

In Eire the notifications of measles went up by 22: 350 of the 403 cases were reported in Dublin C.B.

## Week Ending March 11

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,215, whooping-cough 1,906, diphtheria 624, measles 2,098, acute pneumonia 1,178, cerebrospinal fever 90, dysentery 208, paratyphoid 3, smallpox 2. In the great towns there were 42 deaths from influenza.

## Quarterly Returns for Scotland

The birth rate during the fourth quarter of 1943 was 17.9 per 1,000, and was the highest rate recorded in a December quarter since 1931. Infant mortality was 73 per 1,000 live births—7 above the rate for the corresponding quarter of 1942 and 1 above the average for the five preceding fourth quarters. Stillbirths were equivalent to 36 per 1,000 total births. The general death rate was 15.0, being 2.3 above the five-years average for the December quarter. This increase was mainly due to influenza, bronchitis, and pneumonia, and was greatest in the older age groups. Comparison with the five-years average showed an increase of 2% at ages 25-34, 5% at ages 35-44, 23% at ages 75-84, and 36% at ages 85 and over. 821 deaths were attributed to influenza, the largest number recorded for any fourth quarter since 1918. 57 more deaths were recorded from tuberculosis than in the fourth quarter of 1942. The death rate from all forms of tuberculosis was 75 per 100,000, and that from respiratory tuberculosis was 58. These rates were 7 and 5 above the five-years average.

The preliminary return for the year included in the report shows that the birth rate was 18.9 per 1,000, being 1.2 above the average for the five preceding years. The number of births was the largest recorded since 1928. The infant mortality was 65 per 1,000 live births—9 below the five-years average and the lowest rate ever recorded in Scotland. The stillbirth rate was 36 per 1,000 total births. Illegitimate live births formed 7.6% of all live births, the highest rate since 1929. The general death rate was 13.3 per 1,000—0.2 below the five-years average. Deaths from epidemic diseases numbered 1,947, and were 889 more than in 1942. The increased incidence was due to influenza, which rose from 308 to 1,155, and whooping-cough, which increased from 92 to 305. Decreases were recorded for cerebrospinal fever 180 to 127, scarlet fever 24 to 22, diphtheria 290 to 231, measles 144 to 88. The deaths from diphtheria and scarlet fever were the lowest numbers ever recorded. The maternal mortality rate was 3.7 per 1,000 total births—0.7 below the five-years average and the lowest rate ever recorded in Scotland. Deaths from malignant disease numbered 8,659, being 385 above the average and the largest number ever recorded. A part of this increase may be due to the ageing of the population. Deaths from respiratory diseases also showed an increase, mainly due to pneumonia and bronchitis. The death rates from these two diseases were 63 and 53, compared with 56 and 49 in the preceding year. The marriage rate, 7.6 per 1,000, was 1.9 below the rate for 1942 and is now at the pre-war level.

## Cerebrospinal Fever

The notifications of cerebrospinal fever during the pre-war years showed a seasonal rise, without a definite maximum, during the first half of the year, and the cases were approximately twice those in the second half-year. The range of the notifications was roughly 20-40 and 10-20 in the two half-years. Following the outbreak of war cerebrospinal fever reached epidemic proportions; a maximum of over 600 cases was recorded during the ninth week of 1940. Although the

incidence steadily decreased, it never fell below 5 to 6 times the pre-war level during the year. In the beginning of 1941 the cases rose rapidly to a maximum, and the trend of the disease was similar to that of the preceding year. In 1942 the notifications followed a similar curve but at a lower level. No distinct rise to a maximum occurred in 1943, and the trend of the incidence curve approximated in shape to that of peacetime but at a higher level. The decline in incidence has been continued during the present year, but it is still above twice the pre-1940 level. The course of this disease since the outbreak of war compared with the average of the four immediate preceding years is shown in the graph.

## Medical News

The new Fellows of the Royal Society elected on March 16 include Bryan Austin McSwiney, professor of physiology, St. Thomas's Hospital Medical School; Sir Jack Cecil Drummond, professor of biochemistry, University College, London, and chief scientific adviser to the Ministry of Food; Alexander Thomas Glenn, immunologist, Wellcome Physiological Research Laboratories, Beckenham; William Ogilvy Kermack, research chemist, Royal College of Physicians of Edinburgh; and Guy Frederic Marrian, professor of medical chemistry, University of Edinburgh.

At the meeting of the Medical Society for the Study of Venereal Diseases to be held to-day (Saturday, March 25) at 11, Chandos Street, Cavendish Square, W., at 2.30 p.m., Dr. Nora Wattie will open a discussion on the prevention of pre-natal syphilis. At the meeting on Saturday, April 29, the subject for discussion will be "Results of Treatment of Neurosyphilis."

The sixty-fourth annual meeting of the Mental After-Care Association will be held at Burlington House, Piccadilly, W., on Wednesday, March 29, at 2.45 p.m., under the presidency of H.R.H. Princess Arthur of Connaught. The speakers include Sir Otto Niemeyer, chairman of the Provisional National Council for Mental Health, Dr. J. Bram, of the Polish Medical Services, and Col. Henry Yellowlees, M.D., chairman of the Association. All interested are cordially invited to attend.

Prof. Arnold Sorsby will deliver lectures (1) on blindness in childhood, and (2) on the sulphonamides in ophthalmology at 4 p.m. on March 28 and 30, at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2.

The annual meeting of the Medical Superintendents' Society will be held at B.M.A. House, Tavistock Square, London, on Saturday, April 1, at 2.30 p.m.

A Swiss Society for Tropical Medicine has been founded at Berne under the presidency of Dr. P. Thillot of Lausanne, and an Institute for Tropical Medicine at Basle.

Dr. Jolyot Curie, who was awarded the Nobel prize for chemistry in 1936 together with his wife, has been elected a member of the Paris Academy of Medicine.

## Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.) Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.  
TELEGRAPHIC ADDRESSES—EDITOR, *Atiology Westcent*, London; SECRETARY, *Medietru Westcent*, London. ADVERTISEMENTS, *Articulate Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

## ANY QUESTIONS?

## Vapour Density of Trichlorethylene

Q.—What is the vapour density of trichlorethylene?

A.—The vapour density of a substance is the weight in grammes of a litre of the vapour at N.T.P., divided by 0.09, the weight in grammes of a litre of hydrogen at N.T.P. In general terms, the molecular weight of a substance is twice its vapour density. The molecular weight of trichlorethylene is 131.38: therefore its vapour density is 65.7.

## Solids in the Infant Diet

Q.—At what month or weight should solid food be introduced into a baby's diet? Should a baby receive solid food at 4 months, as some authorities advise? Hitherto I have waited till 6 months or a weight of 15 lb. before advising solids, but health visitors returning from refresher courses are discussing earlier solid feeding.

A.—It all depends on what is meant by solids. It is a sound practice not to give solids until the baby is 6 months old, if by that is meant a meal of potatoes and gravy with milk pudding and risks; but from the fourth to the sixth month a little suitable vegetable purée may be given daily, or a little thin cereal introduced into one or two of the milk feeds. The trouble is that most people when given an inch take an ell, and if too much cereal is eaten by a young baby it will interfere with the absorption of calcium from the bowel. This answer begs the question, "What is suitable vegetable purée?" Mothers should be encouraged to find out intelligently for themselves.

## Wound Shock and Internal Haemorrhage

Q.—Is it possible to teach first-aiders to distinguish between the symptoms and signs of wound shock and of internal haemorrhage? Is, for instance, apathy characteristic of the former, restlessness of the latter?

A.—Most informed opinion now inclines to the view that haemorrhage is the major factor in the production of shock. The clinical picture is therefore essentially identical in simple haemorrhage and traumatic shock. Trauma, however, complicates the picture. Reflexes from the injured area, the pain or infection of peritonitis, the mechanical circulatory difficulty and the poor blood-oxygenation of chest wounds, the vagal stimulation and vasomotor-centre effects of head injuries may be added to the effects of simple bleeding. It is difficult enough even for the expert to unravel the complicated puzzle in any given case of severe injury, and it is certainly impossible to give any clear differentiation to first-aiders. They may be made to understand, however, that, while haemorrhage alone can produce the picture of shock, severe trauma is likely to make the condition even worse. The mental state seems to bear some relation to the blood pressure, apathy being present when the blood pressure is very low, and restlessness when the pressure is higher. The change from apathy to restlessness is often seen as the blood pressure recovers with transfusion.

## Origin and Treatment of Threadworms

Q.—Can you dispel some of my ignorance of threadworms? Where do they originate? Puppies have them when their dams do not. Are the worms in radishes threadworms? What is the best treatment?

A.—Man is the only known host of *Enterobius vermicularis*; other species of the same genus occur in monkeys, but not in dogs or other animals. A free-living nematode, *Heterodera radiclecola*, occurs in the roots of radishes; the eggs, when swallowed by man, are passed unaltered in the faeces, and this, in the past, gave rise to a fallacious description of "a new human threadworm, *Oxyuris incognita*."

Treatment is proverbially unsatisfactory, as is indicated by the variety of therapeutic measures recommended in the literature. Owing to the toxicity of the drugs used and the need for careful supervision to prevent reinfection, all forms of treatment are best carried out under hospital conditions. The following give the best results: (1) *Genitana violet*, oral treatment. The adult dose is 1 g. i.d., that for children 1 c.g. daily for each year of age, not chronological, age, the treatment to be continued for eight days: it should be combined with enemas, to wash the worms out of the large bowel. (2) *Hexylresorcinol*, oral combined with enema treatment. The dose is 1 g. for adults and children over 10; below 10 years, 0.1 g. for each year of age. The drug should be administered in hard gelatin capsules. If the oral dose is given in the morning, 1 soap-sud enema should be given the same evening, the latter to be followed by another enema of a 0.1% solution of hexylresorcinol crystals in water, which should be retained for fifteen minutes. More than one course of treatment may be necessary. (3) *Tetrachlorethylene* treatment is effective, but should be given only under hospital conditions. (4) Probably the most effective anthelmintic against the threadworm is *phenothiazine*, but its use is attended with considerable risk, and is probably justifiable only when other methods have failed. (See *Lancet*, Jan. 17, 1942, p. 86; and *British Medical Journal*, Feb. 7, 1942, p. 191.) The greatest problem is to prevent reinfection, and the treatment of one member of the family is futile if other members are infected. General hygiene is all-important. The patient should sleep alone and wear protective pants to prevent his hands touching the perianal region during sleep; underwear, towels, and bedding should be frequently washed and ironed; toilet seats should be scrubbed with cresol; finger-nails must be kept short and well scrubbed.

## Systolic and Diastolic Variations in Hypertension

Q.—In a case of high blood pressure, whether of the malignant type or of essential hyperplasia, is the difference between the systolic and the diastolic readings to be taken into account in assessing the gravity of a case? I have two cases and their B.P. readings are 190/180, 220/145. They are both cases of the essential hyperplasia type. While one would naturally regard the latter as the more serious of the two, does the enormous difference between the readings of the former case make the prognosis more grave?

A.—The diastolic pressure is generally regarded as being the better indication of the severity of the hypertension because it represents the constant load which the arterial system is carrying and it reflects more accurately the resistance of the peripheral vessels. In essential hypertension the rise of diastolic and systolic pressure is not necessarily a proportionate one. The prognostic significance of the absolute height is difficult to evaluate except in cases with a marked rise. Minor variations in pulse pressure are not of much significance because of the several variable factors involved, such as the rate and the output per beat of the heart. A great increase, such as a pulse pressure of 110, as in the first case mentioned above, is an indication of rigidity of the aorta and great vessels, the effect of severe arteriosclerosis. The prognosis in the first case is therefore that of a case of severe arteriosclerosis without any considerable degree of hypertension. In old individuals with a very rigid aorta such pulse pressures are not very uncommon.

## Turkish Baths

Q.—I should be grateful for information as to the therapeutic value of Turkish baths; what are the indications and contraindications?

A.—Turkish baths act by promoting free diaphoresis and increasing tissue metabolism, thus promoting the excretion by the skin of waste products and tending to loss of weight. Their beneficial effect will be enhanced by free drinking of water during the bath, without which much of the benefit may be lost: constipation, for example, may be caused by excessive dryness of the faeces, and thus intestinal elimination may be hampered. Blood pressure is at first raised, but falls as perspiration becomes established; the bath may therefore be found helpful in cases of moderately raised pressure, but is contraindicated if it is high or if there is arteriosclerosis. The eliminative action is beneficial in gout, but the amount of uric acid eliminated by the skin is negligible in comparison with that by the kidney. In

individuals with sluggish skin action this may be promoted; but if perspiration is not quickly induced unpleasant if not dangerous results may occur. People in sedentary occupations with no opportunity for adequate exercise find Turkish baths helpful, and the shampooing process is useful in this respect, especially if the muscles are well kneaded. The loss of weight, which may be considerable, makes the bath useful in the obese; but the weight is often quickly regained, and unless combined with a strict dietetic regimen the ultimate results may be disappointing. There is a general sedative effect beneficial in functional nervous disorders, and a sense of well-being should be experienced after the bath if it is suited to the case. Perhaps the best evidence in favour is the fact that such baths have had a vogue for at least 2,000 years, which would not have been the case had not the effect been generally beneficial.

These general observations will indicate in what conditions Turkish baths may prove useful, but a word of warning is necessary: if the bathrooms are not efficiently ventilated, cleansed, and disinfected regularly, unpleasant results may occur which are obvious enough without description.

## Exfoliative Dermatitis

Q.—I would like information concerning the diagnosis of exfoliative dermatitis. Is this the same as chronic pityriasis rubra? What treatment is considered most effective, and is anything known about the cause?

A.—The label "exfoliative dermatitis" covers a little-understood group of skin diseases in which there is widespread or universal inflammation and desquamation. Pityriasis rubra is applied to one variety. The exfoliation may be primary, or secondary to some pre-existing eruption, such as psoriasis, or follow ascertainable causes such as treatment with arsenophamine, or be associated with a blood disease (leukaemia). Simple local applications are best, such as boric vaselin; benefit sometimes follows small doses of a stock *B. coli* vaccine, or vitamin B complex.

## Ratio of Corpuscles to Plasma

Q.—On centrifuging blood, it is found that the relative volume of corpuscles to plasma is greater in venous than in arterial blood. What is the reason for that?

A.—The red blood corpuscles are not rigid bodies and their size may be determined from moment to moment by their water content. If R.B.C.s are placed in solutions which are not isotonic to them then water passes across the corpuscular membrane to equalize the osmotic pressures inside and outside the corpuscle. While passing through the capillaries blood takes up carbon dioxide, which is mainly combined inside the corpuscle, as  $\text{HCO}_3^-$ . Although some of the  $\text{HCO}_3^-$  ions migrate through the corpuscular membrane into the plasma, they are replaced by an equivalent number of  $\text{Cl}^-$  ions. The result is that the osmotic pressure of the corpuscular content is increased and water passes into the cell and increases its volume. When the blood passes through the lung and  $\text{CO}_2$  is evolved these processes occur in reverse order.

## Prognosis in Angioneurotic Oedema

Q.—What is the average behaviour of a case of angioneurotic oedema? Do attacks usually recur during a lifetime, or do they cease spontaneously after a time? Can a mortality rate be given for the disease?

A.—Once a person has suffered from one attack of angioneurotic oedema another attack may be expected any time during the remainder of his or her life. The initial attack occurs more commonly after 40 years of age than before, and may accompany or replace another allergic condition. The individual attacks depend upon two groups of factors: first, a specific sensitization to some drug, inhalant substance, or food; and, secondly, a group of factors that temporarily deplete the body's store of protective adrenaline, such as prolonged worries, mental upsets, frequent excitements, overwork, and fatigue. So long as the specific causes have been determined and avoided or removed, and the adrenaline-depleting factors rectified, further attacks are unlikely. No mortality rate can be given as statistics are difficult: some patients die in their first attack; others who get successfully through this immediately consult their doctor in the hope that the ordeal will not be repeated.

## Operation for Otosclerosis

Q.—A deaf patient has read of operations successfully performed which resulted in improvement in hearing. The operation appears to consist of fistulation of the semicircular canals. I should like to know if such treatment is practised to-day, and if so, with what success.

A.—Operation for the relief of deafness due to otosclerosis is based on the observation that an opening into one of the semicircular canals restores hearing, which diminishes again when the opening closes. The problem, therefore, has been to prevent the opening from closing. It is claimed that this can be done by an elaborate plastic operation which utilizes the membrana flaccida and the

membrana tensa with the adjacent part of the external auditory meatus to cover the opening. The opening is said to be more effective the nearer it is situated in the lateral semicircular canal to the vestibule at the anterior end. In order to make this flap lie over the opening, which is made under magnification with fine burrs, the head of the malleus and the incus must be first removed. Absence of any sepsis is essential to success. It is claimed that with a loss of about 50 decibels of hearing a lasting improvement of about 24 decibels on the average can be obtained in about 50% of the cases, and also that deterioration of the hearing may be arrested even if there is no improvement, as shown by persistence of a progressive deterioration in hearing on the opposite side. A rigid selection of cases is necessary, and the possible complications are evident: but these have not been numerous in the hands of those who have attempted these operations.

## INCOME TAX

### New Partnership

"I. B."—A and B commenced partnership shortly before April 5, 1942, B having before then been the sole proprietor. A notice of assessment shows that the partnership is assessed for 1942-3 on the amount of B's earnings for 1941-2. Is this satisfactory?

\* Yes. The rules with regard to cessation and commencement apply to the unit assessed—in such a case as this to the firm and not to the individual partners. As things stand A and B are jointly assessed for 1942-3 in the amount of B's earnings—presumably a smaller sum than the amount of their joint earnings in 1942-3. For example, suppose A to be entitled to one-third and B to two-thirds of the profits, and that B's earnings in 1941-2 were £1,500, then in effect A is charged tax on £500 for 1942-3 and B on £1,000, whereas their earnings may well have been greater. It depends on the figures, of course, but a claim to cessation resulting in both partners paying on their actual earnings for 1942-3 would probably be against their interests.

### Entering the Forces from Eire

"Y. Z." came to Great Britain from Eire on July 5, 1943. He earned £100 as a locum tenens between that date and October 10, 1943, when he joined the R.A.M.C. What is the basis of his liability?

\* Assuming that he has come to this country as an occasional resident and not with the intention of establishing a residence here, he is liable on his earnings in the United Kingdom (and on military pay issued from here even while not so resident), less, of course, the usual deduction for cost of uniform and personal allowance as a married man. He will not be liable on income arising in Eire or from the holding in 3% War Loan. There is no six-monthly period of grace—the six months only applies to income from abroad, and then only if residence in any one financial year does not exceed that period. He should make his return, through the Army Agents, as an occasional resident if that is the fact in his case.

## LETTERS, NOTES, ETC.

### Shock Therapy

DRS. MARGARET M. METHVEN and EDWARD S. STERN (joint secretaries, Child Psychiatry Group, Royal Medico-Psychological Association) write: From the correspondence in the *Journal* regarding shock therapy it appears that there is considerable misapprehension as to its uses. Convulsive therapy is suitable for certain mental disorders in adults, but although we have made inquiry, we are unable to trace a single case where it has been employed in children.

### Thiouracil for Hyperthyroidism

Dr. I. FRIEDMANN (London, S.W.1) writes: With reference to the treatment of hyperthyroidism with thiouracil (*Journal*, Feb. 26, p. 313) may I point out that the use of thiouracil must also be controlled by periodical counts of the white blood cells. In two cases treated in East Ham Memorial Hospital, a marked drop of the white blood cells to 2,000 per c.mm. with 50% lymphocytes followed a short course of treatment with thiouracil. Thiouracil discontinued, the thyroid glands were surgically removed. The histology showed the characteristic features of hyperthyroidism and signs of involution evidenced by cuboidal lining epithelial cells and deep-staining colloid.

### Children's Food Fads

The Hertfordshire County Council has published in a pamphlet the results of an inquiry undertaken by Mr. F. Le Gros Clark on the school child's taste in vegetables. The inquiry was made by an examination of some 400 school essays set at the county schools on "The Vegetables we Eat." The preferences expressed by the youngsters, who were mostly aged between 9 and 11, were very much what was to be expected. The majority dislike parsnips and swedes, turnips are not much more popular, carrots are favoured, though the sweet taste is objected to by some, onions are held in high

esteem, runner beans are well liked, but marrow is detested—"a slimy sort of vegetable," says one child. Children of such tender years are hardly expected to mention the nutritive qualities of food, but 20% of them did so, and about 6% trotted out the word "vitamin." But in spite of Mr. Le Gros Clark's ingenuity and patience there is a feeling that such a study is vitiated unless the kind of cooking with which the child is familiar is taken into account. "Heaven sends us good meat," said David Garrick, "and the devil sends the cooks." When the "meat" is vegetables he sends the worst cooks he has in his kitchen. We grow the best vegetables in the world and ruin them in the pot. The bias against greens among these children might easily be accounted for by the sodden tasteless messes put before them, and the indifference to potatoes, especially when boiled, may derive from the same cause. The school canteen can do much to eradicate food dislikes in children, with great advantage to their nutrition, especially if the mothers at home pay more attention to the saucepan and less to the children's whims.

### Ether as a Cleansing Agent for Wounds

Mrs. M. A. DOBBIN CRAWFORD, M.D., F.R.C.S.I., writes: Minor injuries being of greater importance in war than in peace, continued search is made for a method of treatment which will ensure the least possible disability and loss of working time. To obtain this result, a wound after treatment should be and should remain clean, dry, and undisturbed. The purpose of this note is to redirect attention to a method in use during the last war, apparently by-passed and forgotten. I have seen this method used most effectively during seven years of country practice and have used it during 18 months in a large factory. In the country—remote country, 40 miles from the nearest hospital—every type of injury was treated, the result of hunting, farm, road, and domestic accidents. Not one injury so treated developed sepsis. All the wounds healed by first intention or by clean granulation. A similar result obtained in factory practice. It is a method of extreme simplicity. It avoids the use of any water or antiseptic lotion. The cleansing agent used is ether; the method this:

- (1) The wound is covered by a sterile dressing while the surrounding skin is thoroughly cleaned with ether and sterile dabs.
- (2) The skin immediately around the wound is similarly cleaned.
- (3) Using a Silk's metal anaesthetic can, the wound is thoroughly irrigated with ether, any particle of dirt being removed with forceps or sterile wool.
- (4) Surrounded with sterile cloths the wound is then treated, any dead tissue excised, bleeding-points secured, skin accurately sutured.
- (5) Skin may have a final painting with merthiolate (formerly with iodine, which was also sometimes used in preparation of the skin).
- (6) Dry sterile dressing, to be undisturbed for at least five days, better still a week; if there is loss of skin preventing suture and not requiring graft, the final dressing is with sterile gauze and aerillavine emulsion, again left undisturbed for at least five days.

Similar treatment is used for burns of the first and second degrees. No anaesthetic is required if the blisters are intact. Thorough cleansing of the skin with ether and sterile dabs is followed by removal of the blistered cuticle and dressing with aerillavine and sterile gauze. This dressing is left undisturbed for at least five days while the burned skin heals without interruption; the blistered area will be found clean and dry, the reddened area healed. The patient is seen and is warned to report any pain, but the wound being comfortable is undisturbed. The pain caused during this treatment is not severe and is of short duration. The sting or smart is much less than that of spirit and causes no distress to the average patient who has suffered minor injury. Where the wound is larger or more severe anaesthesia will in any case be needed for repair. There is nothing new about this treatment. Ether was used as cleansing agent for wounds a quarter of a century ago. I saw a knee-joint which had been penetrated by the iron spike of a railing heal without any trouble after excision of the wound and reverse ether irrigation. Gynaecologists many years ago used ether as routine to clean the pelvic peritoneum contaminated by pus during laparotomy. Such experiences of this admirable agent leave me bound to prefer it to any watery solutions which soak the tissues. Their use I can only consider a regression in surgical technique.

### A Warning

During the past two years many complaints and inquiries have been received concerning a Norwegian medical woman, married to a British subject, who was temporarily registered in this country but whose registration has now been cancelled by the General Medical Council. Doctors who receive a visit from this lady would be well advised not to part with money.

### Corrigendum

In the *Journal* of March 18 (p. 411), under the heading "Pruritus Ani and Vulvae," in the "Any Questions?" section, there was a reference to "intensive treatment with vitamins A or B<sub>1</sub>." This should have read, "vitamin A or B<sub>1</sub>."

## AETIOLOGY AND TREATMENT OF CONVULSIONS DURING ANAESTHESIA

ABSTRACT OF A PAPER BY

W. N. KEMP, B.A., M.D.

(Vancouver, British Columbia)

The hypothesis advanced in this paper is that a convulsion or tetany occurring during anaesthesia, local or general, is essentially a muscular phenomenon, caused basically by interference with cell respiration in the brain. In the last analysis nerve-tissue respiration resolves itself into oxidation of glucose. Any factor—and usually several factors are operative at one time in a case of convulsions—which interferes with the vital processes of cerebral cell respiration may cause a convulsion in a patient undergoing operation under either general or local anaesthesia. In the case of local anaesthesia a relative or absolute overdose is needed to produce a convulsion. Briefly stated, it appears that failure of nerve-cell respiration creates a focus of efferent nervous discharge in the cerebral cortex which results in a convulsive seizure. The term "tetany," for the purpose of this discussion, is taken as synonymous with a convulsion of the Jacksonian type. The difference between "tetany" and "convulsions" seems to be one merely of degree.

The conception of failure of cerebral cell respiration as the cause of convulsions during anaesthesia is quite in keeping with the teaching of Penfield and Erickson,\* who state that "when anoxia reaches a critical level it becomes irritating to the central nervous system." The theory also conforms to the teaching of Hughlings Jackson, who maintained that, basically, there was only one physiological cause of epilepsy.

The first cases of ether convulsions were reported in 1927, but it had been known for many years that frank anoxaemia could, and frequently did, cause epileptiform movements and "jactitations" during the administration of nitrous oxide anaesthesia. But the occurrence of convulsions in patients whose blood was not noticeably anoxic is a complication of ether anaesthesia now being reported with increasing frequency, and a phenomenon which to date has baffled solution. Many theories have been advanced in explanation (see Table). Current textbooks on anaesthesia reflect the prevailing lack of unanimity as to aetiology and treatment.

Although convulsions during ether anaesthesia were not unknown before 1927, they were certainly not common before 1924. I had a case (Case 1, below) in that year, but a search of the literature at that time failed to reveal another. In 1927 Pinson, Hornabrook, and Gwathmey recorded cases, and from then onwards cases were reported more frequently, many different causes being suggested. From the list in the Table the divergence of opinion as to the aetiological factor or factors is noteworthy, but in my opinion it only appears to be a divergence. These diverse factors are contributory or accessory, the main or precipitating cause of the convulsion being tissue anoxia arising from acapnia and alkalaemia—a point to be developed later.

Judging from the multiplicity of suggested convulsion-producing factors in the Table, it is probable that no single factor is the cause. Possibly the convulsions may be due to one primary factor—namely, interference with cerebral tissue-

List of Writers reporting Cases of "Deep" or "Late" Ether Convulsions, with Suggested Causes\*

\* Called "deep" and "late" to distinguish them from ether clonus, an innocuous and not uncommon phenomenon of light ether anaesthesia. It is not impossible—indeed, it is very probable—that ether clonus is due to the same cause, in mild degree, as the so-called "deep" or "late" ether convulsions.

cell respiration, brought on by alkalaemia, which is known to cause a form of occult anoxia from failure of the oxyhaemoglobin (OxyHb) of the blood to release its oxygen to the nerve tissues. The alkalaemia is directly due to acapnia (CO<sub>2</sub> deficit) incurred by pulmonary over-ventilation, which in turn is fostered by fear (inadequate sedation), over-atropinization, toxæmia, and elevated metabolism, together with the use of ethyl ether administered by a semi-open technique.

### Case Reports

[Here in the original paper followed detailed reports of eleven cases, all of which had come within the writer's personal experience, although he was not in every instance the anaesthetist in charge of the case. Four, which seem to be typical, are given.]

Case 1.—1924. A female aged 46. Operation:—Exploratory laparotomy and posterior gastro-enterostomy for perforated duodenal ulcer. Anaesthesia:—Ether vapour, with O<sub>2</sub> and semi-open ether technique with mask and damp towels. Convulsions occurred during peritoneal closure after 75 minutes' anaesthesia. Treatment:—Intravenous saline. Convulsions ceased in 20 minutes: uneventful recovery.

Case 2.—1931. A male aged 35. Operation:—Laparotomy and primary closure of perforated gastric ulcer. Anaesthesia:—Intra-

\* Quotations from *Epilepsy and Cerebral Localization*, by Penfield and Erickson (1941), are freely used by kind permission of the publisher, Charles C. Thomas, Springfield, Ill. (Baillière, Tindall and Cox, London agents).

tracheal ether-vapour insufflation with  $O_2$  and no rebreathing. Anaesthesia had continued for 35 minutes and the surgeon was suturing the peritoneum in closure when convulsive movements started in right side of face and spread to right arm and abdominal muscles. Ether was discontinued; the mask of a gas machine was applied to the patient's face and he was made to rebreathe  $O_2$  and his own  $CO_2$ , there being no other  $CO_2$  available in the hospital at the time. Within 5 minutes convulsive movements had ceased and the abdominal closure had been completed. A catheter specimen of urine taken immediately was found to be alkaline. Uneventful recovery.

**Case 3.—1942.** A male aged 29. **Operation:**—Skin graft to face. **Premedication:**—Omnopon gr. 1/3 and scopolamine gr. 1/150, subcutaneously one hour before operation. **Anaesthesia:**—Induction by 0.75 g. pentothal sodium (5%) intravenously, followed by endotracheal administration, with closed circuit circle filter of  $CO_2$ , of  $N_2O$  and  $O_2$ , plus ether vapour. Convulsive movements of legs, abdominal muscles, and arms noted 30 minutes after starting anaesthesia. Blood was hypoxic, and had been so for some time according to surgeon's report. Convulsive movements ceased immediately when the oxygen content of the inhaled mixture was increased to 100%. No further convulsions when anaesthesia with large safety margin of oxygen was continued. Post-operative recovery uneventful.

**Case 4.—1943.** A male aged 26. **Operation:**—Skin graft to left hand. **Anaesthesia:**—Intratracheal nitrous oxide-ether-oxygen following intravenous pentothal sodium (0.5 g.). Closed filter circuit used. When I took over this case anaesthesia had been induced 45 minutes previously and the course had been normal. Pulse was rather faster than usual—110 a minute—and the colour was somewhat dusky. Patient was in second plane of third stage of anaesthesia. Respirations relatively shallow, 14 per minute. Within another 5 minutes of this regimen a violent ether clonus of both the lower extremities started. This was readily controlled by simply doubling the previous  $O_2$  intake and cutting out the  $CO_2$  filter without altering the plane of the anaesthesia. Within 2 minutes the clonus ceased, and within 10 minutes the pulse was down to 90 a minute and the patient's colour was pink.

#### Abnormal Physiology of Clinical Cryptogenic Conditions\*

Penfield and Erickson (1941) have ably reviewed this subject. They divide epilepsy into symptomatic and cryptogenic. The former includes cases in which known aetiological agents, such as brain tumour, scar formation, etc., cause or predispose to convulsions; the latter, that large group of "essential" or idiopathic epilepsies in which the cause cannot at present be found. Consideration of the known factual data as stated by Penfield and Erickson concerning the cryptogenic group may be expected to throw light upon the problem of convulsions during anaesthesia.

Cryptogenic epilepsy begins with an abnormal neuronal discharge in the vicinity of a demonstrably abnormal focus within the central nervous system—what Hughlings Jackson called "the local discharge of grey matter." Holmes pointed out that "local" epilepsy may be focal motor epilepsy, focal sensory epilepsy, visual epilepsy, or auditory epilepsy. For the purpose of this discussion attention will be focused on the first of these varieties. Jacksonian or focal motor seizures are characterized by local movements of some part of the body; in a "Jacksonian march" the spread of movements from one part of the body to another is produced by spread of discharge up and down the precentral gyrus of the cerebral cortex. In the cases cited above the seizures were characteristically Jacksonian in type, beginning with the facial muscles and extending to the abdominal region.

[Here the writer, by means of a series of direct quotations from Penfield and Erickson, drew attention to the clinical data and neurological opinions to be considered:]

"Any normal brain may be the seat of epileptic discharge if it be subjected to the appropriate influence from without."

"More important than electrical rhythm are the causes of the change in cell chemistry that produce dysrhythmia and also the clinical manifestations of epilepsy."

"Studies of the cerebral tissues show that brain metabolism is relatively high. Blood flow through the brain seems to be rapid."

"Blood-flow increases [through the cortex during normal functional activity of any cortical area] would seem to be due to vasodilatation resulting from the presence in the tissue of carbon dioxide, produced by the increased activity of ganglion cells."

\* That is, ordinary cryptogenic epilepsy occurring in patients not under anaesthesia.

"Carbon dioxide in the cerebral tissue causes the local blood vessels to dilate promptly. . . . It [the mechanism] provides increased blood at the time of functional increase and guards against local anoxia which might otherwise occur. . . . Brain metabolism and quantitative supply from the blood stream are quite accurately balanced under normal conditions."

"Complete arrest of the cerebral circulation results almost invariably in a small convulsive seizure. . . . This would indicate that when anoxia reaches a critical level it becomes irritating to the central nervous system."

"Formijne (1938) observed that convulsions occur after the period of asystole. His graphic records indicate that during asystole there is a continuance of respirations with a hyperventilation of the blood stagnated in the lung. With resumption of cardiac function the hyperventilated blood circulates through the respiratory centre and there is a period of apnoea. Convulsions which occur at this same time were therefore ascribed by the author to the action of blood upon the brain. When  $O_2$  and 5%  $CO_2$  were inhaled convulsions failed to occur under these conditions."

"It [hyperpnoea] will precipitate grand mal attacks in from 5 to 30% of the cases. Petit mal seizures are much more easily induced by hyperventilation."

"The plasma pH has been observed by a number of investigators to shift towards the alkaline side prior to the onset of seizures."

"Oxygen and 5% carbon dioxide should be administered if there is cyanosis."

This last procedure was suggested by me (Kemp, 1932, 1933) as one to be followed regardless of the patient's colour—that is, whether he is cyanosed or otherwise.

#### Experimental Considerations

When the parathyroid glands are excised from dogs the thyroid, for anatomical reasons, is always removed as well, and in due course, under ordinary conditions, the dogs develop tetany. This sequel can be controlled by intravenous infusion of calcium chloride solution or by physiological sodium chloride solution. The mere placing of the dogs in a cool room (where they do not pant) has been found to prevent the tetany which otherwise follows thyro-parathyroidectomy, the reason being that a dog, unable to perspire, can lose heat only through its respiratory tract, and when placed in a warm, humid room pants and develops acapnia and alkalaemia, which produce increased muscular tone and convulsions if the dog is predisposed by having a low blood calcium.

Not the least important purpose of breathing is the maintenance of the normal H-ion concentration of the blood. Conditions of clinical acidalaemia or alkalaemia are an increase in this concentration stimulates the respiratory centre. A fatal acidalaemia implies, as Rowntree has well expressed it, an H-ion concentration as "acid as distilled water," and a fatal alkalaemia one in which the blood is as "alkaline as tap-water." Acidalaemia may be due to an increase in the  $H_2CO_3$  or a decrease in the bicarbonate ( $BHCO_3$ ); alkalaemia may be due to a fall in the  $H_2CO_3$  or an increase in the bicarbonate.

#### Clinical Alkalaemia

Wright (1940) points out that there is a tendency towards alkalaemia when excessive breathing at rest occurs owing to voluntary hyperpnoea, to exposure to high temperature and humidity, to lack of oxygen, and, in some cases, to infantile diarrhoea and vomiting; also when the bicarbonate of the blood is increased owing to an overdose of bicarbonate or to pyloric or high intestinal obstruction. Alkalaemia may occur in heat stroke caused by exposure to excessive humid heat. The body in such a condition attempts to lose heat by increased breathing, and the over-ventilation results in acapnia and alkalaemia. This may go on until the heat-regulating mechanism breaks down, the rise in temperature stimulates metabolism, heat production is still further increased, and a vicious circle is established (Fig. 1).

It is reasonably well established that voluntary over-ventilation causes a tendency to alkalaemia (Collipt), and hyperventilation during semi-open anaesthesia may cause acapnia and alkalaemia, a blood pH of 7.7 having been recorded (Adriani 1942). It now remains to show how alkalaemia in the presence of normal blood Hb oxygenation—the usual finding in cases of deep ether convulsions—can cause tissue anoxia and con-

† Personal communication.

ulsions. A consideration of the well-proved data summarized in the haemoglobin dissociation curve (Fig. 2) shows that when tissue activity is markedly increased and the  $O_2$  tension of venous blood falls to 15 or 20 mm. Hg, the blood gives off 70 to 80% of its  $O_2$ , greatly increased quantities of which are thus supplied to the tissues. The presence of  $CO_2$  lowers the

threshold of  $O_2Hb$  dissociation, and thus provides increased quantities of  $O_2$  from venous blood. It would seem from a consideration of these data that a convulsion during ether anaesthesia is a defence effort on the part of the body temporarily to stop pulmonary respiration and exhalation of  $CO_2$  and actually to create  $CO_2$  and lactic acid by muscular action in order to correct the alkalaemia which causes failure of dissociation of  $O_2Hb$  and the anoxia which in turn leads to inhibition of nerve-cell respiration.

## Discussion

At least a dozen factors may influence and limit nerve-cell respiration during ether anaesthesia. These include low oxygen percentage in the inhaled atmosphere; physical obstruction of the patient's airway; subnormal tidal pulmonary exchange; decreased vital capacity; some barrier to normal diffusion between alveolar air and the blood in the pulmonary epithelium; failure in the  $O_2$  transport system; disturbances of tissue respiration; excessive pre-operative pulmonary over-ventilation, and various pre-operative conditions. Furthermore, these also include many secondary or subsidiary contributing factors—as, for example, avitaminosis; prolonged vomiting; secondary anaemia; under-sedation, which allows fear to produce over-ventilation and a tendency to alkalaemia even before anaesthesia has begun. An open or semi-open method of ether administration, while it prevents free access of atmospheric air, allows a  $CO_2$  deficit to be established, assisted by over-ventilation, and thus may be a contributory factor. The use of ether, in itself a respiratory stimulant, may cause over-ventilation and acapnia when Nature requires under-ventilation and  $CO_2$  conservation: it also causes suppression of renal function, and thus the long-term mechanism of blood H-ion regulation is rendered inactive at a time when diuresis and alkali elimination are very much needed. During the administration of semi-open ether anaesthesia, unfortunately for the H-ion regulatory mechanism for controlled elimination through the kidney, the secretion of urine is inhibited by the antidiuretic hormone of the pituitary gland or by some other factor related to the anaesthetic, and no adjustment of the H-ion concentration of the blood can occur by the normal renal mechanism. As we have seen, the only remaining mechanism of H-ion adjustment—that of retardation of respiration—is frustrated by the forced respiratory stimulation attendant upon ether in the blood stream and the stimulating effects which fever, a moist and warm atmosphere, surgical trauma, and the several other factors, some of which are indicated above, have upon the breathing.

Thus a convulsion under ether anaesthesia may be inevitable because the two normal H-ion-regulating mechanisms are both inhibited or subjected to marked interference. There is nothing else for Nature to do but to "seize hold" of the situation and stop respirations and  $CO_2$  loss by attempting a major epileptic seizure while at the same time producing more  $CO_2$  and lactic acid by means of excessive muscular contractions in an effort to counteract the acapnia and alkalaemia which cause cerebral cell anoxias and convulsions.

Taylor (1940) has reported that in a total of 33,777 administrations of cyclopropane and oxygen in the Wisconsin General Hospital and at the Bellevue Hospital, New York, apnoea requiring respiratory stimulation occurred in 248 cases (0.7%) and convulsive movements in 39 cases (0.1%). As cyclopropane is always administered by a "closed" technique, usually in the presence of adequate oxygen, the occurrence of convulsive movements in 0.1% of these cases might be construed as an argument against the theory of acapnia and alkalaemia as the primary cause of convulsions under inhalation anaesthesia. A further study of available data, however, suggests that Taylor's statistics reinforce rather than refute the theory; but owing to lack of space this cannot be further developed here.

## Treatment of Convulsions occurring during Anaesthesia

Treatment is primarily prophylactic, and consists in avoiding open and semi-open administration of ether, particularly when any of the secondary convulsion-producing factors enumerated above are present, and in avoiding large doses of local anaesthetic drugs. Before any operation the patient's urine is usually examined with particular attention to the question of albumin, casts, and white or red blood cells. This urinary investigation should also include a reasonably accurate report on the pH of the urine so that the anaesthetist would be warned of an incipient tendency to alkalaemia. In non-emergency cases the NH<sub>4</sub> excretion could also be reported with advantage, and for the same reason.

The actual treatment of the convulsions *per se* includes:

1. Immediate inhalation of 5%  $CO_2$  and 95%  $O_2$  by a face mask and rebreathing bag.

2. If this does not bring about cessation of convulsive movements within a few minutes, intravenous sodium pentothal in 2.5% or 5% solution (or hexobarbitone or sodium amytal) should be administered in addition to the inhalation therapy described above, and in a dosage adequate to control the convulsion.

3. As soon as the convulsion is brought under control an intravenous infusion of glucose-saline (10% glucose in normal saline) should be started for the purpose of promoting renal function and restoring the normal kidney mechanism of H-ion adjustment (that is, the elimination of excessive basic phosphates and bicarbonates *via* the urine). One litre of glucose-saline might well be given to an adult and 500 to 750 c.cm. to a child. Once the convulsion is under control the anaesthetic and operation may be continued, with the early termination of the latter always in mind.

4. If facilities are available the patient's blood pH and/or the pH of the urine should be checked within an hour after the convulsion ceases, and CO<sub>2</sub> and O<sub>2</sub> inhalations should be given to the point of hyperpnoea or for 5 minutes every half-hour until such time as the blood pH is below 7.5 or an acid urine is being secreted. The reaction of the urine is not as accurate an indication of alkalaemia as the blood pH.

5. Before the patient is returned to bed 2 to 3 dr. of ammonium chloride in six times that volume of water should be instilled by gastric tube into the stomach.

6. As soon as the patient is able to swallow he should be given cool drinks freely, but in small quantities at one time. The basis of the drinks should be physiological saline. Prior to this, rectal saline is indicated.

7. The patient must be kept cool—if possible, in an air-conditioned room; or, failing that, an electric fan may be placed on face and torso.

8. If his temperature remains higher than 102° F. and the atmosphere is warm and possibly humid, a wet sheet may be placed on the patient's thorax and abdomen and a stream of air directed thereon from an electric fan.

9. If his temperature is persistently higher than 102° F. and respiration continues to be rapid, cold 5% glucose-saline enemata may be administered in addition to the measures mentioned above.

10. Inhalations of 5% CO<sub>2</sub> and 95% O<sub>2</sub> must be instituted on the first sign of any facial or other twitching.

#### Summary and Conclusions

Convulsions occurring during the administration of general or local anaesthetic drugs are primarily due to interference with or inhibition of cerebral cell respiration.

The interference or inhibition is usually caused by (i) frank anoxaemia; (ii) occult tissue anoxia due to alkalaemia and acapnia; or, as when local anaesthetic drugs are used, by (iii) the toxic action of the drugs inhibiting the oxidation-reduction enzymes of the tissues.

The principal treatment is prophylactic.

Emergency treatment is outlined.

According to *Presse Médicale* the number of cases of venereal disease in France in 1942 increased by 55% over the figure for 1941. In the Beurmman dispensary 369 fresh cases of syphilis were seen, as against 214 in 1941. In the Department of the Loire the numbers of fresh cases of syphilis for the years 1938 to 1942 rose as follows: 47, 60, 93, 126, and 193.

## HYSTERICAL SEQUELAE OF INJURIES

BY

P. D. SCOTT, M.B., B.Ch.  
*Surg. Lieut., R.N.V.R.*

AND

PAUL MALLINSON, B.M., B.Ch., M.R.C.P.  
*Surg. Lieut.-Cmdr., R.N.V.R.*

(From a Naval Neuropsychiatric Unit)

There is a general appreciation of the influence of hysterical mechanisms in prolonging and intensifying all kinds of ill mental and physical, in Service patients. Where symptoms persist, although there is no longer any evidence of organic disease, the possibility of hysterical prolongation is seldom overlooked. On the other hand, where abnormal physical signs persist despite thorough and rational treatment (especially these signs are definite and striking) psychogenic factors are apt to be neglected. This neglect, with the resulting delay in diagnosis, may be due, in part, to the relative rarity of conversion symptoms in this war compared with the last.

Many factors have probably contributed to the decline in the incidence of hysteria as a primary diagnosis and of conversion symptoms in particular. Of these, the reorientation of psychiatric opinion that has taken place in the intervening years is perhaps one of the most important. It can scarcely be doubted that the form of many hysterical manifestations was largely the product of medical expectation and of medical examinations carried out with preconceived ideas. The search for definite hysterical symptoms and specific hysterical "stigmata" has given place to psychobiological methods with their emphasis upon the assessment of the total personality. For example, as has been pointed out by Stephenson and Cameron (1943), the general recognition of the anxiety state, the early diagnosis of this condition, and its acceptance as a illness requiring and amenable to treatment have tended to make the development of gross physical symptoms, as it were unnecessary.

#### Case Material

The present paper is concerned with a series of six cases all of which were admitted to this hospital during one quarter in 1943, in which a striking and distinctive hysterical disability followed injury to the hand or arm. The clinical picture—a cold, blue, weak hand with impaired superficial sensibility—was rarely enough encountered in an annual turnover of some 1,400 neuropsychiatric admissions to make the series a memorable one. There can have been no possibility of contagion, since all the cases developed in widely separated units or establishments. The following clinical features were shown by the series as a whole:

In all six cases the hand was cold, subjectively and objectively and cyanosed; power was markedly impaired; the skin was soft and shiny. In five of the cases superficial sensibility was impaired or abolished up to a line round the long axis of the limb (in the sixth case the area of diminished sensibility corresponded with the distribution of the ulnar nerve). In four of the cases frank swelling of the hand was present. Disturbances of sweat secretion were spontaneously reported: "I does not seem to sweat properly"; "It sweats more, and feels either very hot or very cold"; "It sweats more"; "Seem dry." The finger-nails were abnormal—in two cases they were thickened, and in two others badly bitten. Repeated injury to the limb had occurred; plaster-of-Paris immobilization had been employed (three of these cases had fractures). In three of the cases there was immobility of interphalangeal or metacarpo-phalangeal joints due to muscular spasm; and spontaneous pain, described as burning or cramp-like, variable in site and intensity.

It is noteworthy that in five of the cases manual dexterity of a rather high order was an essential requirement for carrying out the rating's special duties.

*Case 1 (Wireman, aged 22).*—In July, 1942, this rating fell and dislocated his right elbow. Reduction of the dislocation was followed by limitation of movement at the elbow for some months. In Jan. 1943, after a second fall on to the same elbow, movements again became limited and painful. Detachment of the common extensor origin was demonstrated radiologically, and this was successfully

replaced at operation on Feb. 2. He was then treated with plaster-of-Paris immobilization and an arm-sling for five weeks. At the end of this period there was almost complete loss of voluntary movement in the elbow, wrist, and hand, and he could not abduct the arm at the shoulder. In addition the hand was cold, blue, and slightly swollen. Sensibility to cotton-wool and pin-prick was absent up to a line around the middle of the forearm. This condition persisted until the middle of March, at which time all the muscles gave normal electrical reactions; but he would not use the arm or hand even to feed himself, and the diagnosis of hysterical prolongation of a healed injury to the elbow was made. Full voluntary movements were regained in one session of explanation and persuasion; exercises and P.T. were given for three weeks, when he was discharged to duty with no residual disability.

**Case 2 (Able Seaman, aged 25).**—This rating broke his leg in 1934 and recovered without any residual disability. In 1939 he injured his left hand, which became swollen. He was told that he "had a ganglion" and was given four months' light duty, thus missing his ship. The hand returned to normal during this period. In Aug., 1942, a 4-in. shell fell on to the back of his left hand. Pain and swelling followed, but there was no bone injury. The hand was immobilized in plaster for five weeks, after which, in spite of intensive physiotherapy, it became cold, blue, and swollen up to a line two inches above the wrist. The radial artery pulsed normally, but capillary return in the hand was sluggish. The hand felt stiff, and movements were weak and slow. Superficial sensibility was impaired in a patchy fashion, approximately over the glove area; the upper limit of the impairment coincided with that of the cyanosis and swelling. The nails were thickened and the hand was dry and cold to the touch. He said that when the hand warmed up it did not seem to sweat properly. He also complained of burning pain, mainly in the third finger. Eight months after the injury a diagnosis of hysteria was made, and a month later, following explanation, persuasion, exercises, and physiotherapy, he was discharged to duty with a normal hand.

**Case 3 (Leading Wireman, aged 24).**—In March, 1941, this man sustained a left Colles fracture with fracture of the scaphoid. Good union was secured after five months' immobilization in plaster-of-Paris. Pain and numbness persisted in the wrist, but he was able to carry out full duties. In June, 1942, a second accident caused the scaphoid to be fractured again; once more good union was obtained by immobilization in plaster. Convalescence was prolonged owing to persistent pain and numbness of the wrist and hand, which became cold, blue, shiny, and swollen, with thickening of the nails and loss of sensibility to cotton-wool and pin-prick of glove distribution. All movements of the hand were equally weak, but there was no muscular wasting. A diagnosis of hysteria was made nine months after the second injury; five weeks later he was discharged to duty with a normally functioning hand and symptom-free.

**Case 4 (Air-fitter, aged 22).**—This right-handed rating had a congenital deformity of his right hand (fusion of the fourth and fifth metacarpals and of the lunare and hamate bones). He had been self-conscious about the deformity since boyhood, but it had caused no disability until, at the age of 17, he began to experience difficulty in performing fine movements with the hand and started to use his left hand for writings. He joined the Navy in Jan., 1940, and stood up to a long period of arduous and dangerous service in aircraft carriers, managing to perform his duties without too much difficulty, although still using his left hand more than his right. In Aug., 1942, during severe enemy action, his right hand was caught between a shell and a bulkhead. The injury was slight, causing a small bruise, but from this time he became unable to hold anything in his right hand, which subjectively felt cold and was held in the "claw" position. On this account he was drafted ashore, where the symptoms improved a little until he was required to work on and accept responsibility for the servicing of a type of aircraft which was new to him. He said: "I can't work on fighter aircraft, because my hand goes stiff; I might make a slip-up and get into serious trouble." On admission to this hospital in May, 1943, his right hand was cold, blue, and showed typical glove anaesthesia; the fingers were held in the "claw" position with the thumb adducted. The grip was weak and there was a spasm of the antagonists. A diagnosis of hysteria was made, and after one week's treatment he was writing well with his right hand (for the first time for five years) and had good insight. He was discharged to duty.

**Case 5 (Petty Officer Motor Mechanic, aged 25).**—Two days after he joined the Navy in Aug., 1940, an accident occurred in which he fractured his left elbow, which was immobilized in plaster for eight weeks. Uninterrupted recovery ensued. In June, 1941, soon after joining a motor attack craft, he had to be drafted ashore because, when working below decks at sea, he became anxious and complained of dizziness, weakness, nausea, and excessive sweating. In Oct., 1942, his right arm was crushed between two boats, the shaft of the ulna being fractured. The arm was immobilized in plaster for about four months. On removal of the plaster the arm was weak and movement at the elbow limited. Attempts to move the arm were

painful. Three months later he still complained of pain in the forearm and of stiffness of the elbow, which was then fixed in full flexion by muscle spasm. Hand movements were very weak and painful. The hand was cyanosed and the skin soft and moist. There was impairment of superficial sensibility of glove distribution. The nails were badly bitten. The right hand sweated more than the left and felt subjectively either very hot or very cold. A diagnosis of hysteria was made seven months after the injury; fourteen days later, during which he received psychotherapy, full function was restored and the signs and symptoms had disappeared. He was then discharged to duty.

**Case 6 (Sick-berth Attendant, aged 33).**—In Aug., 1942, he received shrapnel wounds while serving in a landing craft engaged in the Dieppe raid. One tiny fragment pierced the dorsal aspect of his right hand, where it remains, causing no symptoms. A second small fragment passed superficially to the right ulnar nerve from left to right, lodging in front of the internal epicondyle of the humerus. Healing of the wounds was rapid and complete, but the right hand and wrist became "completely paralysed," and the ulnar side of the hand and wrist was tender on pressure and spontaneously painful. A month later he complained of burning pain, numbness, and tingling of the ulnar side of the hand. He could not extend the fourth and fifth fingers, and passive extension caused pain. The fingers could not be adducted to the third finger. The ulnar nerve was felt to be thickened at the elbow. All movements of the hand were weak, but there was no appreciable wasting. Flexor carpi ulnaris, palmaris brevis, adductor pollicis, interossei, and lumbricals responded normally to faradic and galvanic stimulation, but the fifth tendon of flexor digitorum profundus did not respond to faradism. Sensibility to cotton-wool and pin-prick was diminished in the distribution of the ulnar nerve. The hypothenar eminence was tender on pressure. The whole hand was swollen up to the level of the proximal wrist crease. It was cold and cyanosed and the skin was shiny. Sometimes the hand was found to be sweating more than the left. The finger-nails were bitten. A diagnosis of co-contraction of the ulnar nerve was made and physiotherapy was given, but without improvement. By Feb., 1943, the condition was worse, and the fourth and fifth fingers were so flexed upon the palm as to resemble a Dupuytren's contracture. At this time his attitude towards his symptoms was very complacent; he displayed an amused and faintly contemptuous tolerance of the attempts that were made to treat his hand. His knowledge of the presence of an organic lesion and of its nature made psychotherapy the more difficult; but one month after psychotherapy was started he had become co-operative, showed fair insight, and had a hand normal in function and appearance, with full extension of the fingers. Some tenderness on pressure over the hypothenar eminence remained. He was then discharged to duty.

### Diagnosis

This will be considered under three headings:

#### 1. Physical Signs and Symptoms

The principal features have been enumerated above. In all the cases recovery from the original injury had proceeded beyond the point when the residual disability could be directly attributed to it. The uniformity of the physical signs was remarkable, and the clinical picture, when seen, was distinctive enough to bring hysteria to mind at once in the consideration of the differential diagnosis of any similar condition. The striking vasomotor disturbances led, before the diagnosis had been established, to a proposal to perform sympathectomy in Cases 2, 3, and 6. Tests were done in order to assess the probable efficacy of this measure. In Cases 2 and 6 an injection of novocain was made into the stellate ganglion, with immediate temporary relief of symptoms together with the production of a Horner's syndrome.

Physical findings which suggested a "functional" origin were: normal electrical reactions of the muscles; the typical "glove" distribution of the anaesthesia; spasm of the antagonist muscles; absence of appreciable wasting; and the exclusion of arterial disease, arthritis, and the major endocrine and neurological disorders, such as syringomyelia and tabes, in which trophic changes in the hands are known to occur.

There remained for consideration the so-called vasomotor neuroses, or "angioneuroses." To these conditions our cases presented certain similarities. Of the more familiar of them, however, Raynaud's phenomena are characteristically paroxysmal, bilateral, and induced by cold; while erythromelalgia—first described by Weir Mitchell in a sailor—has a disputed pathology in which it is perhaps possible that psychogenic sometimes plays a part. It is said to occur more commonly in the feet than in the hands, and pain is a more prominent feature.

feature than it was in our cases. The onset following trauma, the marked sensory and motor loss, and the readily demonstrated hysterical motivation (see below) served further to distinguish our group. There is a possibility that hysteria is too seldom considered in the differential diagnosis of vasomotor disturbances. In a recent discussion at the Royal Society of Medicine on "Immersion Injuries and Vasomotor Disorders of the Limbs in Wartime" (*Proc. roy. Soc. Med.*, 1943) no mention was made of psychogenic disorders such as those described here.

## 2. Response to Treatment

In all the cases improvement had ceased with physical methods of treatment employed alone.

*Case 1.*—Relatively little time elapsed between the removal of the plaster and the diagnosis of hysterical paralysis. Psychotherapy of a very simple kind, combined with active exercises, resulted in complete recovery in three weeks.

*Case 2.*—The hand was immobilized for five weeks (there was no fracture); symptoms persisted, but the diagnosis of hysteria was not made until seven months later. Psychotherapy was then begun, and recovery followed in one month.

*Case 3.*—The diagnosis of hysteria was made nine months after the injury. Recovery followed after five weeks of psychotherapy.

*Case 4.*—Here the injury was slight and immobilization was not required. The symptoms were severe. The diagnosis was made nine months afterwards, but psychological treatment for one week enabled the patient to write with his deformed hand for the first time for five years, and he was discharged to duty in 2½ weeks.

*Case 5.*—The diagnosis was made seven months after the injury. Complete recovery was obtained after a fortnight's psychotherapy.

*Case 6.*—The diagnosis was made six months after the injury. Complete recovery, apart from a very slight organic residuum, was obtained after one month's psychotherapy.

The basis of treatment was to obtain the patient's confidence and co-operation. The formal psychotherapeutic procedures comprised explanation, persuasion, and suggestion. Re-education and physiotherapy were given at the same time, with certain precautions; the physiotherapist was instructed to "make the patient do all the work," not to discuss the symptoms, and not to use any form of passive treatment, particularly faradic baths, which had been found always to make the symptoms worse. Occupational therapy was arranged to suit the interests of the individual—e.g., in Case 2 boxing was prescribed.

Most of these patients made rapid progress up to a certain point and then "hung fire." At this point they had to be driven hard, and sometimes were subjected to a restriction of their privileges. In all cases these measures were successful, although in Case 6 a threat of transfer to a disciplinary rehabilitation centre was required. In this case, also, continuous traction by means of elastic and plaster-of-Paris was needed to reduce the secondary contracture. Later the normal hand was immobilized for a short time in order to encourage the patient to use the affected one. It was found useful to obtain, for a three-cornered discussion, the voluntary co-operation of one of the group who was improving satisfactorily with one who was lagging behind.

## 3. Motivation

The Committee on Head Injuries of the Medical Research Council (1941) has defined hysteria as "a condition in which mental and physical symptoms, not of organic origin, are produced and maintained by motives never fully conscious, directed at some real or fancied gain to be derived from these symptoms." While the mere absence of a physical basis for complaints is insufficient, and the demonstration of an adequate personal motive is one of the most important of the positive criteria for a diagnosis of hysteria, it need hardly be pointed out that many a severely wounded or physically ill man has as good reason as the suspected neurotic to wish to avoid returning to the dangers and discomforts of active warfare. The discovery of a motive, such as the wish to be invalided from the Service, is by no means pathognomonic of hysteria; the demonstration of previous neurotic traits, of excessive dependency and emotional immaturity, of underlying anxiety, of a "neurotic" attitude towards symptoms or treatment, and of other neurotic features in the personality may provide helpful confirmatory evidence. In none of the cases under

discussion was the motivation in the least obscure. If it is objected that a more prolonged inquiry would have revealed other important psychopathological material, our answer must be that psychotherapy based upon data elicited by the routine methods of psychiatric history-taking and examination enabled all six men to return to duty in a reasonably short time with some insight and with a will to carry on.

*Case 1.*—This man was a simple, stable Scotsman whose personality and past history were free from psychopathic features. After his first injury, movements of the elbow-joint had been very painful, and he had avoided using it so far as was possible, although, since he was back at duty, a good deal of pain was inevitable. The second injury, which resulted in the detachment of the common extensor origin, occurred before movement of the elbow had become painless and before he had regained confidence in it. This injury caused movements to become still more painful, and the hysterical prolongation of the immobilization by plaster was motivated by fear of renewing the pain. He accepted this explanation; he had no wish to leave the Navy, and, once he had been shown that movements were in fact no longer painful, he worked hard to become fit for duty.

*Case 2.*—This patient had experienced prolonged and severe stress in Russian and Malta convoys, including the torpedoing of his ship. His special duties as a member of the crew of an A.A. gun entailed much use of his left hand. He was worried about the safety of his wife, who was living in a target area, and he frankly said: "I think I have done my bit for this war." Three years previously, as the result of an injury to the same hand, he had been given four months' shore service and missed his ship. The second injury was taken more seriously; the hand was put in plaster for five weeks. It was not surprising, in view of the long strain and repeated enemy actions to which he had been subjected and the concession he had gained before from an apparently less serious injury, that the second injury should have been used hysterically to postpone his return to sea. The personality was extroverted and sound.

*Case 3.*—This man's parents had both had neurotic breakdowns, but he himself had shown no evidence of instability, although slightly backward at school. He had been a farm worker and was keen to go back to the land. After twice breaking his wrist, with an interval of fifteen months during which he was at duty, he developed a hysterical prolongation of the second injury, motivated by his desire to be invalided from the Navy. This desire was reinforced by the knowledge that since he had enlisted his job had been made "reserved." His co-operation was obtained, and he accepted his obligation to serve until the end of the war.

*Case 4.*—In this case a congenital deformity of the hand, of which he had always been rather ashamed, acted as a locus minoris resistentiae following a slight injury which occurred during a period of extreme emotional tension and danger. When he was drafted ashore on account of the ensuing disability the persistent anxiety was transferred to his new work—the responsible duty of servicing an unfamiliar type of aircraft. For him a hysterical disability provided a respite from danger and from responsibilities which had provoked a mild but persistent affective disturbance in a vulnerable personality.

*Case 5.*—This man was a long-standing neurotic. He had been a bed-wetter and had had nightmares up to the age of 11 years. He was a chronic head-biter. At home he had often been in minor trouble: "I always preferred to go my own way." His work record was satisfactory, but he had fainted once while at work, and was kept in hospital for three weeks afterwards. He was prone to headaches and attacks of "tightness" in the chest associated with much belching; these symptoms were worse on exertion, but not related to food. He developed marked anxiety symptoms almost immediately after joining his ship, and had therefore to be drafted ashore. Here he worked well enough until he met with an accident, in which his right ulna was fractured. He was a man with a defective health-conscience, in whom hysterical prolongation, as a means of avoiding the anxieties and discomforts of active service, could probably have been predicted soon after he sustained his injury.

*Case 6.*—This man received a nerve injury during a most dangerous action. He had never been to sea before, but had worked satisfactorily in hospital as a sick-berth attendant. This alarming "baptism of fire," coupled with several superficial shrapnel wounds and a temporary ulnar palsy, made him wish to gain an honourable discharge from the Navy. He felt that he had earned this, and he acquired an exact knowledge of the symptomatology of ulnar nerve lesions. He showed the complacency, the power of self-deception, and the logical inconsistencies which are characteristic of the hysterical personality. He had worked in a bank, and although he felt unable to do any kind of work in the Service owing to his disabled right hand (his writing hand), he believed that he could carry out his duties without too much difficulty if he were allowed to return to the bank. As he said, "My manager has only one arm!"

### The Influence of Personality on Prognosis

Two further cases will be briefly described in which psychopathic defects in the personality adversely affected the prognosis. In neither had there been any injury, but the clinical picture did not differ materially from that described above; in both the condition was recurrent. In one case the left hand was affected, in the other the right leg and foot. These two cases were admitted in 1940 and 1942 respectively.

**Case 7 (Ordinary Seaman, aged 29).**—This man came of a Naval family. His father was a Royal Marine pensioner and all his seven brothers were in the Navy. His mother had had several attacks of hysterical paralysis of the hand. He was brought up to join the Navy; no alternative was ever considered. He first joined in 1926, at the age of 15. He disliked the life from the beginning and never settled down, but the family tradition prevented his seeking his discharge. In 1930 his left hand, in the course of a few days, became swollen, painful, and weak. After nineteen weeks in hospital without improvement he was invalided from the Service. He was ostracized by his family and made unwelcome at home. Six months later, his hand having fully recovered, he rejoined in order to be accepted once more by his father and brothers. He concealed his previous invaliding for a time, but after a few weeks it was discovered and he was discharged as a fraudulent entry. Again he was disowned, but a transient recurrence of swelling, pain, and weakness of the left hand three or four times each year prevented his attempting to join the Navy again. He married, and for the next ten years, with his recurring disability as a face-saver, he was able to lead a restricted and lonely life, making no friends and cut off from his family. In Aug., 1940, he rejoined the Navy, but again found that he could not adapt himself to the life, and early in November his left hand became swollen, painful, cyanosed, and weak. He was admitted to hospital with the provisional diagnosis of "subacute rheumatism." Temperature, pulse, sedimentation rate, and radiographs of the hand were normal; there was no cervical rib. Physiotherapy, salicylates, and colchicum brought no improvement, and, in view of the long history and inadequate personality, psychotherapy was not attempted. He showed a marked emotional immaturity and dependency, being still strongly attached to his family, had a violent temper, and had frequently "fainted" at the sight of blood or on experiencing trivial pain. He was invalided as a case of hysteria.

**Case 8 (Ordinary Seaman, aged 36).**—This man's father was invalided from the Navy after the last war for neurasthenia. He was an anxious, depressive, ineffectual person with vague aspirations to become a teacher, although he took no steps to attain this end. He had for the past ten years earned three guineas a week as a pepper-grinder. In 1938, at a time when he was in financial difficulties which culminated in bankruptcy, his right leg "suddenly gave way" as he was rising from his chair, and he fell to the ground. He could move the leg, but it would not bear his weight. He did not see a doctor, but remained in bed for one month. He then began to get about, but complained of cramp-like pains in the calf if he walked above half a mile or if he climbed more than a few stairs. The pain would disappear after he had rested for some quarter of an hour, but the leg remained weak. Meanwhile, as he felt unable to go out, his wife attended to the bankruptcy proceedings, and for the time being relieved him of all responsibility. After a few months his leg ceased to give him any trouble, although he noticed that it had become, and remained, a little "thinner" than the left.

When he joined the Navy in Sept., 1941, he attempted to gain rapid promotion to petty officer by taking a trade test in engineering. He failed in the test and was bitterly disappointed at having to revert to "menial" tasks and less comfortable living conditions. His right leg again gave way, but recovered when he was drafted to another establishment to await a refresher course before attempting the test again. He felt, however, that he would not be successful. He obtained week-end leave, and his leg gave way once more as he left the train after completing his journey home. He was taken to his house and put to bed. Thence, in Jan., 1942, he was moved to a civilian hospital, where a diagnosis of thrombo-angitis obliterans was made and intensive physiotherapy was given without improvement. In March he was transferred to a Naval hospital; here the condition was considered by the medical specialist to be hysterical, and he was transferred to this unit.

On examination there was wasting to the extent of 1½ in. in the right thigh and 1 in. in the right calf. There was extreme weakness of the leg, and he walked with impressive difficulty on two crutches, which he was persuaded reluctantly to abandon. The foot was cold and blue, and trophic changes were beginning in the skin. No sensory changes were found, although inconstant areas of diminished sensibility had been recorded previously. There were no signs of organic disease to the C.N.S., and in both feet the dorsalis pedis

artery pulsed normally. The C.S.F. was normal, the Wassermann reaction was negative in the blood, and there was no evidence of arteriosclerosis. The left leg and foot were normal.

Here again, in view of the psychopathic setting and the probability of relapse, psychotherapy within the Service was considered unlikely to be effective or worth while. He was invalided as a case of hysteria and was offered further treatment in an E.M.S. neurosis centre. He preferred, however, to return home, as he felt that he would "pick up" quicker there and be able to earn his living sooner.

### Conclusions and Summary

A group of cases is described in which physical symptoms and signs of a distinctive character, hysterically produced or maintained, served greatly to prolong convalescence in six Naval ratings who had received injuries to the hand or arm. The importance of the early recognition of such psychogenic complications is shown by the rapid response to psychological treatment of a relatively simple kind, which was followed in all six cases by return to duty. The diagnostic criteria are discussed under three headings: (1) the physical findings; (2) the failure of physical methods alone and the good response to psychotherapy; (3) the demonstration, by the routine procedure of psychiatric history-taking and examination, of hysterical motivation. It is possible that psychogenic factors are sometimes overlooked in the differential diagnosis of vasomotor disorders.

Prognosis depends very largely upon the personality setting in which the hysterical symptoms occur. Two cases are described in which similar physical symptoms developed without previous injury or severe stress. In these patients the personality was markedly psychopathic, and similar illnesses had occurred in civilian life. Both these men were invalided from the Service.

The lay connotations of the term "hysteria" and the social worthlessness of many hysterics have given rise, understandably enough, to adverse moral judgments. These, however, are not justified in all cases of hysteria, and effective treatment, as well as justice, demands that a careful discrimination should be made.

## CHRONIC PULMONARY CATARRH IN CHILDHOOD

BY

A. BRIAN TAYLOR, M.D., M.R.C.P.

Assistant Physician, Birmingham United Hospital

The varying manifestations of recurrent non-specific respiratory infection occurring especially in childhood allow of numerous names and diagnoses being given. Chronic pulmonary catarrh represents a very large proportion of these cases, and this term also usefully describes the condition in the majority. Leys (1927) introduced this name, and his monograph dealt fully with the bibliography and history. He found descriptions of numerous chronic or subacute infective pulmonary conditions under various names which could most satisfactorily be grouped together by this term, which describes the clinical state concisely and usefully. This does not seem to have been adequately noticed, and textbooks and the like do not appear to recognize this common and troublesome condition.

During 1942 there attended my asthma clinic at the General Hospital, Birmingham, 63 children under the age of 14. Most were sent up by their doctors with the general diagnosis of asthma, others for investigation of recurrent bronchitis and persistent or recurrent coughs. In only 12 of these cases did it seem that the condition was a true allergic asthma, the criteria being the previous occurrence of infantile eczema, direct relationship between the attacks and foreign proteins, freedom from respiratory symptoms and signs between attacks, greater frequency in summer months, normal lungs ph-

and radiologically, and response to adrenaline and/or ephedrine. The remaining 51 were examples of chronic pulmonary catarrh, their first diagnosis being variously asthma, recurrent bronchitis, recurrent coughs and colds, etc. In a further group of 38 children, also under 14, seen in private practice for similar symptoms, 33 showed evidence of recurrent catarrhal infections of the respiratory passages, only 5 being cases of true allergic asthma.

The problems of true asthma in childhood have recently been dealt with in this *Journal* (Hurst, 1943, etc.) and numerous papers on the question of allergy have been published—e.g., Bray (1930).

While, doubtless, many asthmatics can be classed in the various groups of allergy, so to regard all of them leads to much disappointment. Skin testing may show sensitivity to proteins, but these are usually so varied as to make the knowledge of little value, whereas many others show no positive reactions at all. Chronic pulmonary catarrh appears to be the chief factor in the majority of the more or less non-allergic cases, and of the present group of 101 children 84 had associated underlying respiratory infections. Recurrent colds or upper respiratory catarrhs were followed by generalized pulmonary effects—coughing, tight chest, wheeziness, and more or less "asthma." In other cases persistence of cough was the most troublesome complaint. Most of the children seemed to show an increased susceptibility to respiratory infections, or else had a chronic infection which was lighted up by unduly trivial circumstances such as changes of weather, exposure to cold winds, damp, fog, rain; and all the attacks were more frequent during the winter and early spring months. Cameron (1926) has emphasized this type of "catarrhal child."

An impression has also developed that with the continuance of the war the natural improvement usually occurring in the spring and summer has been delayed or impeded, suggesting an underlying slight degree of hypovitaminosis or fatigue. During the period of heavy air-raiding the use of air-raid shelters was also evidently detrimental. Geographical effects have been noted in the aetiology: the plateau on which Birmingham stands is 450 to 550 feet above sea-level, far inland, and exposed to south-westerly winds, and the soil is largely clay.

### Clinical Features

The clinical picture of the attack varies greatly. In some children it is mild, and is referred to as a bronchial cold with slight pyrexia and cough; in others the asthmatic features are predominant, with laboured wheezy breathing and prolonged difficult expiration. In another group a mild pneumonic attack seems to occur. The duration and termination also vary considerably, though the slowness of resolution and of disappearance of cough is most noticeable. The acute asthma picture often lasts several days and is followed by persistent wheezing and a cough, especially troublesome at night or by exertion with extra respiratory activity. The physical signs during the attack also vary and are not pathognomonic. Prolonged expiration is usual, but rapid shallow breathing is not uncommon. Rales and rhonchi may be heard anywhere, but especially posteriorly, and, significantly, they are almost always bilateral.

Between the attacks the child may be quite well, but one usually finds shallow breathing, poor development of the thorax as evidenced by round shoulders, flattening anteriorly and Harrison's sulcus, and coughing after deep breathing or exertion. Pharyngitis is often present as well, and large infected tonsils and post-nasal catarrh may be seen. These are certainly not always present; and often they have been treated, but without the expected recovery. While it is desirable to remove chronic upper respiratory infection, many parents are disappointed by the failure of such treatment to prevent the recurrent pulmonary attacks.

### X-ray Appearances

Radiographic changes are common. The movements of the diaphragm are usually restricted. In the cases with an asthma tendency the thoracic cage is deformed, the ribs having an upward tendency from the excessive inspiratory efforts. The chest, too, tends to rise on inspiration instead of expanding. The lung roots are unduly heavy, suggesting glandular enlarge-

ment. The striations radiating therefrom are thick and increased, especially to the lower lobes, but often into a zones. The lung parenchyma itself may have a slightly woolly appearance. One of the most important points is the bilateral and symmetrical nature of the changes. During or immediately following an acute exacerbation there may be shadow of pneumonic consolidation in individual parts of the lung and films taken a few weeks later show these to have disappeared.

Bronchograms show normal bronchi. Occasionally bronchiectasis may simulate or complicate chronic pulmonary catarrh but, in the group of cases that this paper is meant to illustrate distortion or dilatation of the bronchi has not been noticed. Bronchography has been carried out on four of the cases in this series and on others, sometimes as part of the routine investigation and at other times when rales have persisted between attacks or when there has been more copious sputum. Clubbing is unusual.

### Diagnosis

A number of cases have been tested with tuberculin, usually by the Mantoux, and the results are not different from what one would expect in their age group. In considering the diagnosis two points arise: first, the question of nomenclature; secondly, the differential diagnosis. Leys (1927) in his exhaustive monograph has reviewed the historical aspect and shown how the term "chronic pulmonary catarrh" usefully describes this common condition, which numerous authorities have seemed to diagnose under fibrosis of the lungs, fibroid lung, recurrent bronchitis, unresolved pneumonia, interstitial pneumonia, chronic bronchopneumonia, peribronchitis, and so on. Few necropsies have been recorded, and though chronic inflammation and fibrosis occur, it seems more desirable to use a clinical appellation rather than a purely pathological term.

Differential diagnosis has to be made from true allergic asthma, which has already been discussed; and also from bronchiectasis and tuberculosis, both of which have in the past been commonly mistaken for chronic pulmonary catarrh. The former is marked by the exudative nature of the symptoms, and the sputum persists and is purulent between the attacks. Bronchography easily decides the presence or not of dilatation, but now that one can correct clinical impressions thereby it is evident that the two conditions produce quite different pictures. Tuberculosis is often suspected, but the course of this disease has usually not the intermittent character, chronicity over years, and marked effect on the rate and quality of breathing. Radiologically the appearances may be similar, but the lesion in tuberculosis is especially in the parenchyma of one lung, whereas the catarrhal lesions affect the bronchi and bronchioles. The tuberculin test will often help to decide the issue if there is doubt, especially in children. Macpherson (1943) has shown the incidence of a positive Mantoux reaction in children, and under the age of 14 years it can be of great value.

True asthma is often difficult to distinguish. During an acute attack the symptoms and signs are the same—whether the result of spasm of the bronchiolar muscles or of oedema and congestion of the bronchiolar mucous membrane. A negative result from skin tests, no history of other allergic manifestations previously or in the parents, the definite relationship to catarrhal conditions of the throat, the slower recovery, persistence of signs between attacks, radiological changes, and lack of response to adrenaline and ephedrine are among the critical features of chronic pulmonary catarrh.

### Treatment

In the acute attack treatment is that of acute bronchitis, asthma, or pneumonia, depending on the predominant features. On the other hand, the important thing is to reduce the frequency of the attacks and to limit the permanent damage that may result. Frequent and prolonged absence from school and increasing pulmonary fibrosis and emphysema may damage the prospects of these children very materially. There is no doubt that climatic measures can give the best results. In peacetime, wintering in Switzerland for several years has proved most satisfactory. There seems to be a tendency to grow out of the condition, or at least the susceptibility to it as

the child reaches adolescence; and if the ill effects can be prevented by avoiding the attacks for some years, much of the danger has gone. Other warm dry climates abroad are available, but economic as well as international difficulties preclude their help. In England the south and south-west coasts are valuable, but many inland districts are also reliable. From Birmingham many parents send their children to school in the Malvern district, and this relieves the majority. Open-air schools of the local authorities are also beneficial, particularly when they are found in sandy, sheltered, and warm situations.

In wartime especially, these measures are largely impracticable. Also, parents at any time are often loath to part with their children in their early years, and especially when they are delicate. For these cases breathing exercises have been found of extreme value. Their use has been increasing steadily in recent years, especially with the greater knowledge of the mechanism and physiology of the respiratory apparatus. Hurst (1927) has clearly described the main points, and the Asthma Research Council (1934) has also helped to popularize them. Livingstone and Gillespie (1935) have published some results which indicate their value.

The principal points required are to correct faulty posture and movement of the thoracic cage, to promote diaphragmatic movement, to increase respiratory excursion and resilience, and to improve expiration. Douthwaite (1930) has also indicated these points. There is no doubt that the disciplinary effect of these regular exercises is in itself of much benefit, and at the same time insistence on nose-breathing can obviate much of the reinfection and recrudescence of infection from the pharynx.

Teaching the exercises to the children may be done in a group, and I have a clinic at the General Hospital under the charge of Mrs. Brown, head of the massage department. This has the advantage of stimulating the team spirit and encouraging regularity, and of initiating new patients. The alternative is treatment individually, or perhaps in pairs. It is then easier to arrange times to avoid school hours, and with some of the more nervous or difficult children better control is obtained. It is essential that the exercises should be done regularly and daily, and regular supervision by the masseuse makes a great difference in keeping them correct and adequate. At my clinic the children attend twice weekly, and the mothers are also taught the exercises so as to make the children do them on the other days. It is essential to continue the treatment for months or years, and most failures or relapses are due to leaving them off too soon or to want of care in doing them regularly and persistently. The results are seen rapidly. The frequency of the acute attacks is reduced; the attacks are shorter; between the attacks the child is better, healthier in general, loses its cough, and becomes less susceptible to catarrhal infections. The condition seems to diminish naturally as the child grows up, but adequate treatment usually relieves it sooner, and so reduces invalidism and loss of schooling; also it obviates most of the permanent ill effects that may follow, such as chronic bronchitis, emphysema, and fibrosis of the lungs.

The general management of the child must also be watched and clothing and exercise be adjusted. Feeding is often difficult, but common-sense management is needed, especially as these patients can often be classed among the "nervous child" group (Cameron, 1929). As Cameron points out the nervous child is particularly prone to catarrhal infections, whether from a lack of immunity due to chronic upper respiratory infection or from weak vasomotor defences. It is always necessary to remember the neuropathic tendency associated with most cases of asthma, recurring pulmonary infections, and the like. It is important, as Hurst has emphasized, that the child should not think he is an invalid.

#### Summary

The term "chronic pulmonary catarrh" describes a clinical syndrome common in children, causing recurrent respiratory "attacks," often suggesting asthma, but associated with inflammatory changes in the lungs. They cause much trouble to the parents and interfere with the child's development.

The symptoms, signs, and x-ray changes are described.

Treatment is most satisfactory by climatic measures, but, at the present time especially, breathing exercises are proving very valuable

and will relieve the majority of cases. It is essential that they should be controlled competently and be continued over a prolonged period.

## SURVEY OF VITAMIN C LEVEL IN WARTIME IN PREGNANT WOMEN

BY

A. ALISON CRAIG, M.D., D.P.H., D.C.H.  
*Assistant Medical Officer of Health, Bristol*

F. J. W. LEWIS, M.B., Ch.B.

AND

DOROTHY WOODMAN, M.D., M.Sc.

(Department of Preventive Medicine, University of Bristol)

The question of vitamin deficiency in wartime is one which is often under discussion. Vitamin C has perhaps excited the most interest because of the lack of fresh fruit and, to some extent, vegetables in present-day diet. Though the clinical symptoms of scurvy, which is the typical manifestation of vitamin C deficiency, may be absent, it is becoming recognized more and more that subclinical deficiency may be present to give rise to other less definite symptoms. The normal requirements of the body in order to prevent scurvy are usually stated to be 25 mg. of vitamin C a day, though Codville *et al.* (1938) believe the real needs of the body to be 100 mg. daily. Glazebrook and Thomson (1942), in their investigation on boys with tonsillitis, found that a supplementary dose of vitamin C to the normal diet reduced the duration of the disease. None of these boys, moreover, developed rheumatism or pneumonia, as did a small percentage of controls not receiving the supplementary dose. It would appear, therefore, that a higher dose than 25 mg. daily would prove beneficial to the maintenance of good health.

During wartime there have been various reports on the degree of saturation with vitamin C. Harris (1942), using the saturation tests described by Harris *et al.* (1935), investigated children in residential homes, elementary-school children, and university students. By comparison with results obtained under pre-war conditions he found that the average saturation curves for April, 1941, were lower than those for 1939. He also found a seasonal variation, the results being low after winter and better after summer. Francis and Wormald (1942) also investigated students. Their results after 9 months of war were not much different from those of a similar group 12 months earlier. After 21 months of war, however, a greater degree of unsaturation was found. More recently, Kohn, Milligan, and Wilkinson (1943) gave a preliminary communication on levels of vitamin A and C in school-children. They found that 72% of the control group were unsaturated, but that in the group which had received supplementary vitamins all were found to be saturated after three months' tests.

#### Present Investigation

It was considered that it might be of interest to examine a group of pregnant women with reference to their degree of saturation with vitamin C under wartime conditions. These women, though receiving certain extra rations—e.g., milk, and in some cases blackcurrant juice—have probably a greater drain on their resources owing to pregnancy. By collaboration with the doctor of an ante-natal clinic it was possible to choose the patients according to their degree of intelligence and power to co-operate. In all, 40 women were tested at monthly intervals on their visit to the clinic. They received a special form in which to record their diet for the week previous to the test, with special reference to fruit and vegetables. It was obviously impossible to control their diet or to take samples for vita-

content, but, in any case, the results on present-day ordinary meals were what was required. Five non-pregnant women were tested each month as controls. The saturation test employed was that described by Pemberton (1940). This test does not reach the same peak as that described by Harris *et al.* (1935). Pemberton, however, obtained comparative results on two groups of boys—one group on a basic diet and the other on a supplemented diet. He was able to show a marked difference between the two groups. Harris's method is definitely better as it covers a slightly longer period, since the last specimen is not passed till 3 or 4 p.m. Owing to transport difficulties it was impossible to arrange for the women to bring back specimens later in the day, hence the decision to use the shorter method. The first specimen of urine was passed at 9 to 9.15 a.m. (Specimen A); a test dose of vitamin C of 70 mg. per stone of body weight was then taken. Urine was again passed at 11.15 a.m., but was discarded; and again at 1 to 1.15 p.m. (Specimen B). This latter one represents the specimen after the test dose. Only a cup of water, as recommended by Pemberton, was allowed to be drunk after the test dose. The urine was collected in special bottles containing a known volume of glacial acetic acid. Vitamin C was estimated in Specimens A and B by the method of Harris and Ray (1935), the dye being standardized each time. The number of monthly investigations varied with the different cases, as some were evacuated before confinement; but an average of five were done on each woman, making over 200 in all. The whole range of the experiment extended from May, 1942, to Feb., 1943, when, owing to unavoidable circumstances, it was impossible to complete the full year.

The results are given in four tables and a graph. Table I depicts the average amount of ascorbic acid excreted by the five controls both before and after the test dose. It also

shows the range for each period. Table II is similar to Table I but relates to the 40 pregnant women. These results are plotted as a graph. Table III gives the average percentage excretion of ascorbic acid per patient for the first 28 weeks of pregnancy and for the remaining period.

TABLE II.—Average Amount of Ascorbic Acid excreted by 40 Pregnant Women

Tests	Dates	Specimen A: Range before Test Dose (mg. per 100 c.c.m.)	Specimen B: Range after Test Dose (mg. per 100 c.c.m.)	Average before Test Dose	Average after Test Dose
10	6/5/42- 2/6/42	0-0.7	0.3- 53.0	0.34	9.44
16	3/6/42- 30/6/42	0-1.2	0- 82.3	0.30	26.9

Average after test dose per whole period and whole group = 43.512 mg.

### Health of Subjects

With regard to the controls, their health with one exception was good throughout save for the usual colds. There was no evidence of anaemia or bleeding gums. The one exception may be worth mentioning as she lived with another of the controls, and therefore had practically the same diet. From May, 1942, to October, their results rose together; but from November to January one of them fell considerably below the other, although still receiving the same diet, and in January she developed influenza followed by bronchitis, and was off work for five weeks. The clinical history of the pregnant women was fully investigated by the clinic doctor. Of the 40 women examined, 3 suffered from both spongy gums and anaemia, 6 others from spongy gums alone, and 8 from anaemia alone. Apart from these symptoms, only the complications associated with pregnancy developed, such as toxæmia and pyelitis, and even these in only a small proportion. This incidence of anaemia—27.5%—is considered by the clinic doctor to be definitely more marked than in pre-war days. With regard to the number of cases of spongy gums, both the clinic doctor and the ante-natal dentist to whom the patients

were sent are of the opinion that the incidence is definitely increased as compared with pre-war days.

The average results on the above 17 pregnant women showing symptoms are recorded in Table IV.

### Discussion of Results

Three main points are shown up by the results. In the first place there is a wide variation in the degree of saturation as judged by the amount of ascorbic acid excreted after the test dose. To economize in space, tables showing each individual excretion are not given, but the variation in the control group lies between 0.4 and 266.7 mg., and in the pregnancy cases between 0 and 345.6 mg. Pemberton (1940) also found variations in his children—namely, 0.5 to 2.6 in those on a basic diet and 13.1 to 74.0 in those on a supplemented diet. One would expect wider variations in our cases, as there was no definite basic diet. Variations occurred from month to month, but where there was a marked rise this appeared to depend on the diet and, incidentally, the season of the year. This leads to the second point—namely, the seasonal variation in both groups. This is well illustrated in the graph. No precise figure for the exact level for saturation following the test dose has been found because, as Harris *et al.* (1935) state, "the test dose does not set out to measure an 'all or nothing' effect—rather, it measures a degree of response or saturation." The average amount excreted per test was worked out for the whole period of the experiment. That for the controls was 43.5 mg., as against 39.7 mg. for the experimental group. Neither of these figures represents a high degree of saturation, and thus it can be assumed that anything below is definitely on the low side. Taking this as our basis, we find in the graph that the real rise towards saturation begins near the end of June for the controls, and near the beginning of August for the pregnancy cases. This rise remains above the average level till November for both groups. The third point of significance is the height of the peak in the two groups. The controls show a much higher peak of 133 mg., as opposed to 86 mg. for the pregnant women.

Most of the investigations on vitamin C in pregnancy have been carried out by workers abroad. The majority show that there is a deficiency in this condition, though Imaz and Gascon (1941) state that, while some change occurred as pregnancy progressed, the limits were found to correspond to normal cases. They conclude that, given an adequate diet, there is no deficiency of vitamin C during pregnancy. Neuweiler in 1935, using the saturation test, found the following range: 8–125 mg. for non-pregnant women, 2–54 mg. during pregnancy, and 2–28 mg. during lactation. He concludes that the utilization of vitamin C is greater in pregnant than in non-pregnant women, and still greater during lactation. Gaehgins and Werner (1937) found a deficiency which was rather more marked in multiparae than in primiparae. Investigating the serum ascorbic acid, Elmy and Christensen (1938) found it was diminished during pregnancy. They also concluded from their investigations that the winter diet from October to April was insufficient as the source of vitamin C—a fact which has been confirmed by our findings. De Rezende (1939–40) and Portnoy and Wilkinson (1938), using Rott's test, found that the tissues of pregnant women were deficient in vitamin C and that this deficiency increased as pregnancy progressed. We have worked out the average excretion per person for the first 28 weeks of pregnancy and the remaining period (Table IV). There is only a small difference between the two, but it suggests a slightly lower saturation in the latter part. The finding that the excretion is lower in pregnant women than in controls thus confirms previous observations. That the latter show an earlier rise is also probably due to this fact, since any diminution during pregnancy would tend to lower not only the peak but the time at which the peak is reached. The explanation for this decrease in saturation was well defined by Teel *et al.* (1938), who, finding that the vitamin in the cord plasma was greater than that in maternal blood, deduced that the foetus acts parasitically on the mother.

Our results appear to indicate that, though at the present time the degree of saturation of both groups is low, there are certain periods during the summer months when it rises and the diet would seem to be more adequate. The increased

incidence of anaemia as suggested by the clinic doctor may not be due to lack of vitamin C only but to other factors. With regard to the spongy gums, it would appear from clinical evidence that more cases are occurring than in pre-war days. The results of our experiments, however, show no definite indication that they are associated with lack of vitamin C. This may play a minor part, but no conclusion can be arrived at from the small number of clinical cases reported by the ante-natal doctor.

### Summary

A group of 40 pregnant women were examined in respect of their degree of saturation with vitamin C under wartime conditions.

Results showed that there is a wide variation in the degree of saturation, and that it is on the low side.

There is a marked seasonal variation, the patients becoming definitely more saturated from June to October.

We would like to express our grateful thanks to the Colston Research Committee for a grant in aid of research expenses, and to Mr. K. G. Moreman for his technical assistance.

## SUDDEN DEATH IN LABOUR

BY

R. G. COOKE, M.D., D.R.C.O.G.  
Medical Superintendent, City Hospital, Derby

The following is an account of sudden death occurring during normal labour in an apparently healthy young primipara, in whom a congenitally small aorta and a persistent thymus gland were found to be present post mortem.

### Case History

Mrs. A. B., aged 22; primipara; well-developed muscular woman. No history of any illness. Had attended ante-natal clinic regularly and appeared to be a normal case. On June 2, 1943, at 9.30 p.m. pains started, and at 11.45 p.m. she was admitted to hospital. Term. R.O.A. Blood pressure 136/90. No albumin in urine. General condition good. Strong pains every 15 minutes. Foetal heart normal.

June 3, 1943.—1.30 a.m.: Three fingers dilated; membranes intact. 2 a.m.: Half an ounce of routine sedative mixture given; general condition good; foetal heart normal. 3 a.m.: Membranes ruptured; fully dilated. 3.5 a.m.: Patient became unconscious, cyanosed; breathing stertorous, limbs flaccid; strong pains every one or two minutes. 3.20 a.m.: Pulse rapid and weak; not so deeply unconscious; reflexes present; arms rigid; legs flaccid; diffuse macular rash on trunk and limbs. 3.25 a.m.: Child born—stillborn. 3.40 a.m.: Placenta expelled; normal loss; ergometrine 1 c.cm.: condition of patient poor but uterus well contracted; warmth; intravenous plasma; oxygen. 4 a.m.: Patient recovered slightly; semi-conscious, muttering, and restless. 4.30 a.m.: Patient deeply unconscious again; pulse weak and thready; condition very poor. 5 a.m.: Condition becoming hopeless; acutely restless; pupils dilated and fixed. 5.45 a.m.: Death.

*Post-mortem Report.*—Heart normal size. Right side relatively empty; this was opened *in situ* and found to contain about six air bubbles, but the blood was not frothy and no bubbles were in the pulmonary artery. Multiple subendocardial haemorrhages in the left ventricle. Valves normal. The aorta was notably small in diameter, measuring only 34 mm. in circumference. Other blood vessels normal. The thymus persisted. Upper air passages clear. The pleura and lungs were perfectly normal, with no trace of pulmonary oedema. The thyroid was slightly enlarged and showed some nodules. Lymph glands not appreciably enlarged. There was ascites of 2 to 3 pints; the fluid was straw-coloured and slightly blood-stained; the peritoneum was otherwise normal. The stomach

bowels were normal except for the distension of the latter with gas. The liver was of normal size, but notably pale. Gall-bladder was normal, and filled with very pale bile. The spleen was twice the normal size, and was red and soft. The suprarenals and pancreas appeared normal. Kidneys normal except for some dilatation of the right pelvis and ureter. Bladder normal. Uterus recently delivered; placenta had been attached at fundus posteriorly; well contracted, normal, no tears of cervix. Bruising of vagina. Tubes and ovaries normal. Skull, meninges, and brain all normal; no cerebral oedema, etc.

**Section Reports.**—The thyroid shows patchy epithelial hyperplasia and increase in stroma, but no appreciable lymphocytic infiltration. The thymus (see Fig.) has typical Hassall's corpuscles. There is

Illustration showing (1) the persistent thymus gland; (2) small aorta from patient (circumference 34 mm.), with, for comparison, (3) normal aorta from adult (circumference 51 mm.) and (4) normal aorta from boy aged 12 (circumference 41 mm.).

hypertrophy of the pituitary, with many basophilic cells. The heart muscle appears normal. The liver shows an extensive tendency to necrosis in the central and intermediate zones, but this is in an early stage. The kidney shows some swelling and early necrosis of the convoluted tubules, and a fairly extensive deposition of brownish pigment in the collecting tubules especially. The pigment does not give an iron reaction. The uterus shows hypertrophy of pregnancy and some decidua; no inflammatory changes.

Death was apparently due to shock. The persistent thymus, small aorta, and nodular goitre evidently gave her a morbid predisposition to shock. The shock was apparently the result of a very rapid birth—the whole labour taking only about six hours instead of the usual 18 to 24 hours in a primipara. The aorta was very small, the circumference being only 34 mm. (see Fig.). The normal circumference for an adult female is about 51 mm., and the normal circumference for a boy aged 12 is about 40 mm. The circumference was measured at the level of the sixth thoracic vertebra.

The patient had had a sister who had died suddenly at the age of 9 while playing. There was no injury. It was on the occasion of a special Sunday-school event, and she was excited. Necropsy and inquest: death due to status lymphaticus.

#### Discussion

The association of a small aorta with a persistent thymus is evidently a matter of importance. Millar and Ross (1942) measured the aorta in many cases of death from accident and disease: the circumference was smaller in those dying from accident, though not grossly so. They consider that a narrow aorta is evidently able to provide for the ordinary needs of the body, but may be unable to cope with sudden emergencies, and may lead to accidental death. In considering the syndrome of status lymphaticus—persistent thymus, enlarged lymphoid tissue, poor development of the arterial system, especially in aorta calibre—they are of the opinion that developmental arterial hypoplasia is the most reliable guide. Moon (1942) says: "A small percentage of human beings have a group of associated anatomical features—hyperplasia of lymphoid tissue, hypoplasia of heart and arteries, etc. A few individuals are liable to die unexpectedly from trivial and inadequate causes: such cases occur almost exclusively among the anatomical group described." Temple Grey (1937), in discussing causes of sudden

death, mentions cases occurring in energetic young adults in whom the heart and aorta are small for the size of the body and in whom some thymus tissue usually persists.

German authors Kehrer and Romberg (1936) think a persistent thymus may precipitate death in obstetrical complications, and quote cases of placenta praevia, renal lesions, haemorrhage, anaemia, and version. Kehrer quotes a case in which sudden death occurred during a version, and the patient was found to have pronounced status lymphaticus with a greatly narrowed aorta. Romberg considers that the process of labour alone may be responsible for sudden death in such a patient.

A further case also occurred at this hospital about a week after the one described above. A 3-para aged 22—an unbooked maternity case—was sent in with a severe post-partum haemorrhage. She was dead on arrival, and at the necropsy a persistent thymus and a small aorta were present.

#### Summary

A case is described in which sudden death occurred in labour in an apparently healthy woman.

At necropsy a very small aorta was found to be present along with other signs of status lymphaticus.

A similar case in normal labour is not traceable in the literature on an ordinary search, although the condition does not appear to be unduly rare.

The small aorta will render the patient more liable to peripheral circulatory failure, especially if some shock-producing condition is present—e.g., rapid labour.

It is suggested that this condition may be a contributory factor in uninvestigated deaths occurring during abnormal labour and may also be responsible for some of the unexplained deaths in normal labour which are not fully investigated.

I am obliged to Dr. G. R. Osborn for the pathological reports, to Dr. R. J. O. Taylor for assistance with the translations, and to Sergt. Fayers for the photographs.

## Medical Memoranda

### Amoebic Abscess of Spleen

Amoebic abscess of the spleen is very rare, and when it does occur is usually associated with amoebic hepatitis. In this case there was no clinical evidence of liver involvement.

#### CASE RECORD

On April 1, 1943, an Indian girl aged 12 was brought for examination. She gave a history of pain in the left lumbar region of 30 days' duration and swelling in the same region for 21 days. She had no urinary symptoms and passed a normal stool once each day. She had been under observation elsewhere for 15 days, and during this time had had a temperature ranging between 99° and 104° F. Her pulse rate had varied between 90 and 110. Quinine and sulph-anilamide had both been given without effect.

The child had obviously lost weight. Her pulse was 110 and temperature 103° F. The heart and the respiratory system showed no abnormality. On abdominal examination her spleen was found to extend downwards and forwards to below the level of the umbilicus, and was extremely tender. The liver was neither enlarged nor tender. The haemoglobin percentage was 60, the red blood count 3,400,000, and the white blood count 13,400—neutrophil polymorphs 80%, lymphocytes 18%, and large mononuclears 2%. The morphs showed no abnormality. A provisional diagnosis of amoebic splenitis was made, and a course of emetine, gr. 1/2 daily for 10 days, was begun.

On the following day, April 2, cysts of *Entamoeba histolytica* were found in her stools. On April 5 her temperature reached 103° F. and a fluctuating swelling had developed below the left costal margin and over the spleen. From this, 40 c.cm. of pus was aspirated. The pus was similar to that from an amoebic abscess of the liver, was sterile on culture, and no organisms were found in smears. No *E. histolytica* were seen in it. After this aspiration her temperature never rose above 98.8° F. On April 9, 10 c.cm. of typical amoebic pus was aspirated. On May 5 the patient was free from pain, her spleen was not palpable, and she had no disability.

## Reviews

### FRACTURES AND JOINT INJURIES

*Fractures and Joint Injuries*. By R. Watson-Jones, M.Ch.Orth., F.R.C.S. Volume 11, third edition. (Pp. 550; illustrated. 75s. per set of 2 volumes, plus 1s. postage.) Edinburgh: E. and S. Livingstone, 1943.

The third edition of this work has of necessity been divided into two volumes, of which the first dealt with the general principles of treatment while the present volume deals with the various fractures and injuries in detail. The high standard of the first volume is fully maintained and the second is of even greater interest than its predecessor. It establishes a new standard in precise description and apt illustration, both of the injuries and of the methods by which they can be corrected. Scarcely a statement is made without an apt illustration, either photographic or diagrammatic, to clarify its meaning. The subject is, in fact, treated in such detail that the book is exceedingly difficult to review, and we can only recommend those who are interested in fractures to read it for themselves. As an example we might refer to the first chapter on injuries to the shoulder and to the short section on rupture of the supraspinatus tendon. Nothing could be more effective than the description of its causation, the diagrams of the lesion itself, and the precise description of the author's own technique for its relief. Injuries around the elbow, which are so common and so often the source of trouble to the surgeon, are discussed with equal lucidity, and our only fear is that the young surgeon may scarcely appreciate the immense difficulties which would seem to be so easily resolved. But perhaps the high light of the book is in the treatment of fractures of the neck of the femur by the modern nailing operation, where the method is described so precisely that it would seem difficult to make any mistake.

The whole book is profusely illustrated, often with great ingenuity, and we would again express our appreciation of the flaps which conceal key diagrams until the reader has been deceived by an apparently perfect x-ray photograph. The author deserves congratulation on a brilliant achievement in a work of use not only to the expert but to all who may ever have to treat a fracture.

### THE TANGLE OF OCCUPIED EUROPE

*Occupied Europe, German Exploitation and Its Post-War Consequences*. (Pp. 75, 1s. 6d.) London: Royal Institute of International Affairs, Chatham House, St. James's Square, London, S.W.1.

This booklet describes Germany's mobilization and exploitation of the resources of occupied Europe up to the autumn of 1943, and some of the problems to be faced during and after liberation. Within the occupied and satellite countries independent economic life has ceased to exist; all has been harnessed to the German war machine. The methods adopted and the results achieved in this nefarious undertaking in the various occupied countries are succinctly outlined. This enables the reader to gain some insight into the immensity and complexity of the problems that will face the United Nations when the overthrow of Germany has been secured. Should the release of occupied countries be gradual in the wake of advancing Allied armies the devastation of battle-grounds added to present scarcity will enhance the difficulties and urgency of relief. Should there be a simultaneous release of all occupied territory following a German collapse, the need for widespread relief and rehabilitation will present formidably complicated problems. The movement of millions of persons—war refugees, foreign workers who have been conscripted for slave labour in Germany, and prisoners of war—all anxious to return home at the earliest moment, will have to be controlled. Such control is important not least from the public health point of view. The organization and co-ordination of health services will be an urgent necessity.

A section of the booklet describes the setting up of U.N.R.R.A., its organization and functions. The task of unravelling the tangle of occupied Europe promises to be one of the most stupendous tasks to which mankind has ever set its hand.

### CONSERVATIVE TREATMENT OF PYORRHOEA

*Textbook of Periodontia (Oral Medicine)*. By Samuel Charles Miller, D.D.S., F.A.C.D. Second edition. (Pp. 733; illustrated. 50s.) London: Henry Kimpton, 1943.

This is an American book about the conservative treatment of pyorrhoea. That this aspect of dentistry is considered to be of the greatest importance at the New York University College of Dentistry is shown by the fact that the textbook is written by an associate professor of periodontia with the co-operation of four assistant professors, seven instructors, and fifteen special contributors, and that it runs into over 700 pages. The contributors presume that almost any case of pyorrhoea is suitable for treatment even when the teeth are loose. That they have evolved a most elaborate technique and are full of enthusiasm for the results they have obtained is beyond question: they are indeed fortunate in having so many persevering and conscientious patients. The operation of gingivectomy, which is the basis of the conservative treatment of pyorrhoea, is performed all over the world with varying degrees of success. The details of this procedure are well described and must stimulate British dental surgeons to careful consideration of their own techniques. The cure depends so much on the post-operative routine of dental hygiene that many of the disappointing cases seen in this country are the result of the patient himself not appreciating the part that he has to play to obtain a lasting result. The American does seem to understand this better than we do, and the chapters on this subject are helpful. Much is said about the medical aspect of pyorrhoea from the aetiological point of view and as a basis of treatment, but too little stress is laid on the importance of the mouth as a focus of infection. Periodontal disease can be the cause of much ill-health and serious illness, and conservative treatment of it is no guarantee that the infection has been eliminated.

### Notes on Books

SIR IAN FRASER, M.P., has added another to his great services on behalf of his fellow-blinded by compiling a pamphlet published for the British Council (Sir Isaac Pitman and Sons, Ltd.; 1s.) entitled *Learning to be Blind*. Briefly it describes the experience of three great institutions—St. Dunstan's, the National Institute for the Blind, and the National Library for the Blind. In a series of cheerful pictures it illustrates the many callings open to blind men and women, the sports and games they can enjoy, and the approximation to normal social life which they can achieve. The approximation is so close that in many of the pictures the photographer has evidently had difficulty in indicating that the people shown are blind at all. It is mentioned that at the present time nearly 250 blind masseurs and masseuses are actively engaged in their profession. One drawback was that they could not administer electrotherapy because of their inability to read the instrument showing the passing of the current; but a simple clamping device has now made it possible for the blind operator to feel the needle of the instrument without damaging it, and now all blind masseurs and masseuses are trained to undertake electrotherapeutic work under medical supervision.

The South Travancore Medical Mission (London Missionary Society), situated in the extreme "toe" of India, has had 19 medical missionaries since its work began just over a hundred years ago, six of them Fellows of the Royal College of Surgeons of Edinburgh and nine others Edinburgh graduates. None of them shows as long a record of service as the present chief of the medical staff, Mr. T. HOWARD SOMERVELL, F.R.C.S., who joined the Neyoor Hospital over twenty years ago. In the report of the Mission, carrying the story to May of last year, Mr. Somervell writes about his long experience. He has pursued the policy of cutting down the numbers of dispensaries and small branch hospitals and of concentrating on institutions larger and well equipped and situated in places of convenient access. Although the Mission now has only half the number of branches that it had in 1923 it has three times the number of hospital beds, and the chief hospital at Neyoor has every facility for modern treatment except deep x-ray therapy. The report also contains the first impressions of the newest recruit, Dr. N. E. James, who writes that the advanced state of some of the diseases in India has to be seen to be believed. The first case of cholera he ever saw reminded him of "an air-raid casualty without any wounds."

The *Presse Médicale* of Paris recently celebrated the 50th anniversary of its foundation on Dec. 23, 1843.

## Preparations and Appliances

### AN ALL-PURPOSE ANAESTHETIC MACHINE

Dr. ERNEST I. BIEBER, honorary anaesthetist, Chester Royal Infirmary, writes:

It has always been difficult to obtain an all-purpose anaesthetic apparatus that is both efficient and extremely portable. Alexander and Fowler, Ltd., of Liverpool have produced an apparatus which fulfils most excellently all the requirements of modern anaesthesia. The illustration shows the head only, but the complete outfits comprise both portable and theatre stands.

It consists of a rectangular metal box, 6½ in. deep × 5 in. × 4½ in. Three small rotameters are contained in a recess in the

ALEXANDER &  
FOWLER LTD

front of the box; they are calibrated for oxygen, cyclopropane, and nitrous oxide. Fine-adjustment valves which operate them are mounted on a panel directly below. Two small levers on either side of this panel control by-passes and provide a means of increasing the flow of  $O_2$  and  $N_2O$ . A push-button on top of the machine enables full oxygen to be given in an emergency without the necessity for altering the fine-adjustment valves. The ether control valve and a three-way tap are placed on top of the box; this tap enables the gases as they issue from the rotameters to be passed either direct to the facepiece, over the surface, or actually bubble through the ether.

The ether container can be replenished or emptied by means of a filler placed behind the ether control valve, while an aperture at the back of the box enables the level of the ether to be readily seen. A tapered mount to which is fitted a soda-lime canister, an adjustable air port, and a half-gallon rebreathing bag fit directly to the right-hand side of the box. The canister, which is provided with a combined expiratory valve and an absorber by-pass, is fitted with perforated diaphragms to ensure even distribution of the exhalations through the soda lime.

The wide-bore rebreathing tubes, afferent and efferent, come from the left side of the machine and are adapted to an "E" piece which carries the mask. Inside this "E" piece are two non-return valves which control the direction of the respiratory tide. A third small-bore tube runs from the machine with the respiratory tubes; fresh gases are conducted directly to the mask by it. The design of the valves ensures a minimum obstruction to the respiratory tide, their position at the face-piece reducing dead space to the minimum, and ensuring more perfect absorption of  $CO_2$ .

If ether vapour is required, the control valve on top of the box enables any fraction of the warm exhaled gases coming from the absorber via the rebreathing bag to be passed over the evaporating surfaces placed in the ether container. The ether valve is constructed to allow vapour concentration to be increased so gradually that no interruption of the respiratory rhythm occurs.

During administration atmospheric air to any amount can be added to the circuit by means of a single ball bellows which can be plugged into the aperture on the right-hand side of the box. This air port may be used for the introduction of ethyl chloride into the circuit if required as an induction agent. At the end of the administration the combined contents of the bag and circuit can be voided through this port and the patient re-educated to breathe atmospheric air. A vinesthene drip feed may be plugged on between the machine head and the afferent tube if desired.

I have been using this apparatus for the past 18 months and have given every type of anaesthesia with it, from simple

dental anaesthetics to intratracheal anaesthesia with controlled respiration, and have found it most satisfactory in use. The outstanding features in its design and construction are its portability, easy adaptability to various circuits, and simplicity in operation. In addition, it has the advantage that where there is a low-pressure supply of gas and oxygen, as on a theatre trolley, the machine head can be used directly from this.

### APPARATUS FOR UTERO-TUBAL INSUFFLATION

ALBERT SHARMAN, M.D., Ph.D., B.Sc., M.R.C.O.G., Royal Samaritan Hospital for Women, Glasgow, writes:

The use of utero-tubal insufflation with carbon dioxide for the determination of tubal patency or non-patency in cases of sterility—it is both diagnostic and therapeutic—is now universal. Many types of apparatus have been employed since the method was first described by Rubin in 1920. The addition of a kymograph in 1925 enabled Rubin to record the graph of the insufflation: the pattern gave definite evidence, not only of normal tubal patency, function, and non-patency, but also of tubal dysfunction and pathology—e.g., spasm and stenosis. All who have used the kymograph agree that it is a most valuable adjunct.

The apparatus described here is the most recent one manufactured, and it incorporates the main features first devised by Rubin, and subsequently modified by Bonnet.

Carbon dioxide is supplied by a cylinder, enclosed within a metal container. A spare cylinder is also enclosed, allowing for constant use of the instrument while the empty cylinder is being refilled. A reducing valve reduces the pressure of the gas to atmospheric (approximate) when the apparatus is in use. On the front panel of the instrument are mounted (1) the dial of the flow-valve, (2) a pressure gauge indicating the amount of gas in the cylinder and the point at which it requires recharging, (3) the main valve of the  $CO_2$  cylinder, and (4) a close-and-shut valve. The rate of flow of the gas can be accurately regulated by moving an indicator on the dial of the flow-valve till it faces the figure corresponding to the desired rate (anything up to 100 c.cm. per minute).

Above the panel there is fitted a special type of recording manometer which records on a revolving drum, in ink, pressure variations during tubal insufflation. The drum, 9 cm. in diameter and 13 cm. in height, is provided with interchangeable sheets of chart paper; it is driven by a small synchronous motor (alternating current) at about one revolution in five minutes. The recorder charts are marked to read up to a pressure of 250 mm. of mercury, which is the maximum pressure recommended. The Rubin uterine cannula is used with the added Bonnet device for altering the level of the rubber nozzle, whereby the pressure of the latter against the extended cervical os may be increased as desired.

A compartment in the case (which is made of wood) houses the electric plug and flexible lead, the cannula, and its connecting rubber tubing. The chart papers also are enclosed alongside by means of clips. The case is fitted with a carrying handle and with clip-hinges for swinging the top cover back when the apparatus is to be used. The whole apparatus is compact and portable, the overall dimensions of the case being 13½ in. × 12½ in. × 8½ in., and the total weight approximately 22 lb. Each cylinder when full should supply enough  $CO_2$  gas to do not fewer than 200 insufflations.

The apparatus is made by Kelvin, Bottomley, and Baird, Glasgow, S.W.

## BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 1 1944

## FLUORINE AND DENTAL CARIES

"Caries has with justice been referred to as the most ruinous of dental maladies, not only in childhood but at every epoch of life. . . . I think it well worth consideration whether the reintroduction into our diet, and especially into the diet of child-bearing women and of children, of a supply of fluorine . . . might not do something to fortify the teeth of the next generation."<sup>1</sup> We are only now beginning to appreciate the truth of this suggestion, made by Sir James Crichton-Browne just over 50 years ago. Modern interest in the connexion between fluorine and the teeth dates from the early 1930's, when it was shown that too much fluorine in the food and drink led to a disfigurement or mottling of the teeth. At the same time, however, experimental evidence was accumulating to show that a certain amount of fluorine might be rather a good thing. Workers in America,<sup>2,3</sup> England,<sup>4,5</sup> and other countries noted that there was less than the average incidence of caries in communities in which mottled enamel was common. The drinking-water is probably our chief source of fluorine, and Dean and his colleagues<sup>6,7,8</sup> have made extensive studies indicating a relation between the amount of fluorine in the water, mottled teeth, and freedom from dental caries. They have shown that this freedom from caries applies to both the temporary and the permanent teeth, and it affects the anterior teeth more than the molars. Furthermore, in an area of endemic fluorosis the caries incidence in teeth that are mottled is the same as in those that are not, indicating that the reduction of caries is not the result of the mottling *per se* but rather of the intake of fluorine.

The optimum concentration of fluorine in the water is thought to be about 1 part per million. Below this level the caries incidence is high. Above 4 p.p.m. there is a danger of a severe degree of mottling with pitting. A very pretty comparison<sup>9</sup> has recently been made of the incidence of caries in North and South Shields. These towns, on opposite sides of the River Tyne, appear to be similar in climatic, social, and economic conditions, but the water supply of North Shields contains less than 0.25 p.p.m. of fluorine, while that of South Shields has a fluorine content of 1.4 p.p.m. The incidence of caries in the permanent teeth in 12-year-old children in North Shields was approximately double the incidence in South Shields.

Fluorine that is ingested while the tooth is being formed is incorporated into the tooth substance, but it seems an

important point that fluorine can protect the teeth from caries even after they are fully calcified. Evidence for this has come from epidemiological studies<sup>10</sup> and from animal experiments,<sup>11</sup> and various attempts have been made to discover the mechanism at work. The enamel of caries-resistant teeth has been reported to contain increased amounts of fluorine.<sup>12</sup> The problem seems to be whether the fluorine reaches the hard tissues of the teeth via the blood stream and pulp, or whether the enamel itself combines with fluorine as it comes in contact with the saliva, the drinking-water, or the food. Rats have generally been used for these investigations. The caries is induced by feeding coarse particles of corn or rice, but rat caries so produced is not entirely analogous to human caries, for the lesions are mainly of the occlusal surfaces. In human caries it is usually the smooth surface of the enamel that is affected. However, dental caries in the rat remains the closest counterpart of human caries that can be brought about in experimental animals, and the caries-producing action of the coarse corn diet is undoubtedly lessened if the diet is supplemented with fluorine. Arnold and McClure<sup>13</sup> studied the effect of giving rats on a coarse corn diet sodium fluoride subcutaneously, and found no reduction in the incidence of caries. Sognnaes<sup>14</sup> tried the local application of potassium fluoride to the teeth of rats on a caries-producing diet, and found that the incidence of caries was half as high as it was in a control group not being treated with fluoride. It cannot be the presence of fluorides in the saliva that explains the effect, however, for rats from which the salivary glands had been removed showed the usual reduction in dental caries when fluorides were given by mouth.<sup>15</sup> Furthermore, very little fluorine is found in the saliva, even after the injection of relatively large amounts intravenously.<sup>16</sup> A preliminary note on the effect of the local application of a solution of sodium fluoride to children's teeth has recently been published.<sup>17</sup> It appeared to reduce the incidence of caries by 30 to 40%.

The conclusion that must be drawn from all this work is that in fully erupted teeth fluorine is adsorbed by the enamel directly from water while it is in the mouth. Evidence that fluorine has a special affinity for tooth substance is forthcoming from other sources. Fluorides have been shown to react with powdered enamel and dentine just as they do with other basic calcium phosphates, and the solubility of the tooth substance in acid is thereby decreased.<sup>18</sup> It appears from the evidence available that fluorine protects the teeth by combining with the enamel, thereby making it more resistant to the products of bacterial action in the mouth. A large-scale human experiment comparing the effect of using a water with 1 p.p.m. of fluorine and a dentifrice containing fluoride merits an extensive trial under well-controlled conditions. The effect of sucking tablets containing fluoride, as suggested by Broderick,<sup>19</sup> should possibly also be included in the

comparison. Prophylaxis in the future may lie, not in regulating the amount of fluorine in water supplies but in legislating for the compulsory inclusion of specified amounts of fluorine in every dentifrice that is sold.

### IS SECURITY HARMFUL?

The fundamental problem for the welfare of any community is that of getting the best possible from its individual members. What is best is susceptible to a variety of definitions. Different communities have adopted different standards at various periods of their existence. Those who run a competitive individualistic society—or at least some of them—have no doubt of the way to get the best—in the sense of the most—out of an individual in the interests of one of the competing groups within that society. Their aim is to maintain a state of economic insecurity in the common man by preserving a surplus of labour and the correlative power to “sack.” The efficient working of this doctrine depends fundamentally on fear—fear at different levels of individual social integration: fear of starvation, of inability to maintain the home, and of loss of prestige. Is this doctrine biologically sound—that human beings perform best when they are insecure in material ways or, indeed, in any other way? The author of the Beveridge report, for example, evidently thinks not. The question is a fundamental one: for the reorganization of society as well as for determining the useful limit of schemes for social welfare.

The evidence from psychiatric experience on the whole supports the view that the creation and the maintenance of a situation of insecurity do not make for maximum efficiency. The doctrine in question is thought by many to be made scientifically respectable by evolutionary theory; but this view depends upon a misreading of Darwinism and its subsequent modifications. It is a hopeful sign that medical men are becoming more and more aware of their responsibility in guiding the thoughts of the community in matters that go to the very roots of the success of a society. Just as the individual as he matures has the need to develop a general point of view or a philosophy which will guide him in the major issues of life, so it is not less necessary for whole societies to have a systematic set of working principles deduced from the study of experience and undergoing a progressive evolution. Tradition after a time loses its force in a progressive society, which must continually try to abstract from its experience so as to profit by it more. It is here that sociologists, by their analysis of different patterns which have evolved spontaneously, can guide development in the directions most likely to be productive. Medical psychologists are especially in a position to do this because they see constantly the effect on human beings of blindly following traditional social convention and economic practice. The ancient Greeks, so eager to discuss the latest new thing in the market-place, would possibly find it difficult to understand our stress upon the value in our educational system of the study of the past.

It is a sign of the increasing awareness of the part that medical sociologists could play that the Royal

Medico-Psychological Association has recently summarized the evidence in support of the Beveridge plan for unemployment insurance. The report of the R.M.P.A. stresses the deplorable effects of mass unemployment. As well as the purely financial consequences there is the psychological harm that comes from fear and depression, and the inferiority feelings that arise from loss of social prestige. Mannheim among others has emphasized the need for work in the maintenance of a man's self-respect. The possession of a job is far from being simply a question of monetary reward. Accordingly the R.M.P.A. recommends not only a subsistence allowance but machinery for the rapid reinstatement of the man or woman in industry somewhere else when local conditions make local employment impossible. Reinstatement should occur before apathy has time to set in. The R.M.P.A. adopts the view, which is the product of experience, that it is only insecurity—for example, in the shape of uncertainty of employment or inadequate benefit—that produces malingering. What is required is not safeguards against malingering but medical and psychological help for social failure resulting from intellectual, temperamental, or neurotic handicaps. It is to the interest of the community to provide, not as little but as much as it can, for all those who are willing to play their part in it. The war has shown that what matters, even more than death itself, is the severance of home ties and the break-up of family life; and it is especially the latter that any scheme of subsistence allowances and rehabilitation must provide against. How often one has heard from individuals coming from families who had been through bad times of prolonged unemployment that “the whole family just lost hope.” In adults the inner discipline that results from good education is a far healthier safeguard against laziness than a permanent threat of external deprivation.

It seems that the answer to the question, “What is the best incentive?” does not lie in the negative, deterrent threat of the “sack” but in the positive incentive of a knowledge of security so long as one is willing to work; and very few people are unwilling. There is no more deplorable example of the narrow, merely financial, view than the failure to recognize that work means more than money which runs through the British system of Workmen's Compensation, where no attempt is made to provide for the reinstatement of the worker on a job except by forcing him by means of a meagre and diminishing allowance to return to his former job, if he can get it, or to eling to it long after he is medically unfit to do so. The sense of insecurity, the resentment, and the litigation that the present system induces, as well as the comparative futility of a lump-sum payment, are now increasingly recognized. It should be our responsibility to see that in any process of rehabilitation, vocational guidance and psychiatric social work are both brought into use. Psychopathic individuals should be rehabilitated in special centres of their own. The whole apparatus of the administration of sick benefit should be humanized, and Labour Exchanges so reformed that they lose their aspect of alms and suffering associated with the bad old days of the dole. The whole trend of these recommendations made by the R.M.P.A. displays the realization that security is not

harmful; that the average human being will tend to rise to his opportunities, and that those who prefer to remain sick, like those who break down in war, are proper subjects for psychiatric examination.

## MEDICAL ASPECTS OF PARACHUTE JUMPING

The U.S.S.R. first developed parachute jumping, both as a sport of civilians and as a valuable technique in offensive warfare. Even before the present war began they had made an exhaustive study of the medical aspects of the subject, the results of which were collected in a book by G. P. Greifer<sup>1</sup> in 1939. The Anglo-Soviet Medical Council has recently supplied an abstract of this, translated by H. Wareing. The whole approach to the subject is summed up by the observation that "parachute injuries, as has been proved by experience, are the result of carelessness in medical selection of parachutists, and inefficient training for and organization of parachute jumps." The major part of the work, therefore, deals directly or indirectly with selection, and it is interesting to find that, although physical examination is exhaustive and the list of rejecting disorders formidable, it is the psychological aspects of selection which have been studied most fully and found most profitable.

Repeated jumps at short intervals have been found to have a deteriorating effect, and even after single jumps there are changes in pulse rate, blood pressure, and urinary constituents, even including albuminuria and hyaline casts. Excluding the physical effects of structural disorder, such as hernias, incompletely united fractures, or an acute infection, the transient changes have all a psychological explanation, established by observation of jumpers, which is made on the ground, in the aircraft or on the training tower immediately before jumping, and on landing, time and time again. Their appearance and behaviour are noted and correlated with the physical changes which are found. All kinds of fear reactions are found in unsuitable pupils, including states of stupor or agitation. It is observed that persons with an unstable nervous system interrupt their training, are accident-prone, make foolish and catastrophic mistakes, and cannot deal efficiently with an emergency. Any evidence of functional or organic disorder of the nervous system is therefore a contraindication to jumping.

Trainees may be divided into four groups according to their behaviour in the plane before the jump. The first and largest (76%) are lively and excited, with rapid speech, flushed face, bright eyes, changing expressions, and general restlessness. The second (14%) are apprehensive—they look worried, preoccupied, and have pale faces, dilated pupils, and a dull expression. The third (3%) are depressed, indecisive, lethargic, and apt to be motion-sick, and the fourth (7%) are a mixture of the second and third. The first group jump confidently after one flight; the second need two or three, while the others will probably be failures. The selection appears to be based much more upon the man's reaction to his job than upon an initial assessment of his personality, and in this respect it is in line with the present tendency in the selection of air crews in this country and in the U.S.A. It is accompanied by a rigid medical examination similar to that used in the R.A.F., but it is followed by a vigilant follow-up throughout training. The man's successful progress is encouraged by a carefully controlled regime, which includes elaborate physical training and a course of education, the emphasis being again upon the psychological benefits rather than the purely

physical. Accidents and injuries are all regarded as avoidable. Errors in jumping account for 5%, and 95% are due to mistakes in landing; but the selector and teacher are blamed—not the pupil. Of the landing accidents 65% result from failure to observe the rules, which prohibit landing on irregular or frozen ground, in a strong wind, and so on, while 25% are caused by bad landing technique, particularly in relation to leg position, the commonest injury being to the ankle or knee, though spinal injuries occur from indirect violence.

Some of the attention to the details of safety which is enjoined in this admirable book is impracticable in wartime, where the technique of parachute jumping differs for high and low altitude. Two papers have recently been published in Germany by Diringsbofen<sup>2</sup> and Gauer<sup>3</sup> on the safety time limits which the jumper has at high altitude. The problem is to determine the correct procedure to prevent fatal effects from anoxia. The alternatives are to delay opening the parachute until the altitude is low enough to sustain life, risking the possibility of being insufficiently conscious to pull the cord, or to open the parachute immediately, risking death from prolonged anoxia. Resistance to anoxia is increased by hyperventilation on oxygen before jumping, and then holding the breath for as long as possible. The breath can be held for about a minute from 36,000 feet, which would enable the man to reach nearly 20,000 feet, at which height the parachute can be opened with safety. It is undoubtedly easier to discuss the ideal procedure than to put it into practice, but the Russian monograph makes it quite clear that actions enforced by rigid training will become automatic, turning a hazardous undertaking into a safe procedure.

## TOXIC TANNIC ACID

One of the most remarkable changes in surgical fashion concerns the treatment of burns with tannic acid. Introduced in 1925 by Davidson, it soon gained widespread adoption and was at the outbreak of this war accepted as the orthodox treatment, for which was claimed not only a satisfactory local effect on the burn but also some degree of control of the general effects. Since the outbreak of war it has been almost universally condemned on both counts. It is now not only regarded as an unsatisfactory, and by some a dangerous, local dressing, but it is also held responsible, as a liver poison, for some of the toxic effects hitherto attributed to burns. While the former may still be a matter of opinion, the latter seems to have been clearly established both by experience in human burns and also by animal experiments. In 1938 Wilson and his colleagues<sup>4</sup> described lesions of the liver in fatal burns, and subsequently came to suspect that these were due to tannic acid. Recent observations of his have not been published, but they were taken up by Cameron and his colleagues,<sup>5</sup> who demonstrated the toxicity of tannic acid to animals and showed that the drug could be absorbed from burns. Further confirmation of Wilson's work was afforded by Barnes, Rossiter, and Clark.<sup>6,7</sup> From America, Wells, Humphrey, and Coll<sup>8</sup> reported four fatal cases of human burns treated with tannic acid in which central lobular necrosis was a conspicuous feature, and they produced similar lesions in small animals by injection of tannic acid. Further evidence from animal experiments is contained in two recent papers. Baker and Handler<sup>9</sup> caused liver necrosis in rats and mice

by injection of the drug and also by immersing the animals in a solution after denuding the belly of skin. Hartman and Romence,<sup>10</sup> working with dogs, found that some animals developed central necrosis with untreated burns, but that the incidence was increased by local application to the burn or by injection of tannic acid and also silver nitrate and mercuric chloride.

While caution is necessary in applying to human beings the results of animal experiments on burns, it should be noted that suspicion first fell on tannic acid as a result of experience in human burns, and animal experiments have been used only to obtain confirmatory evidence. It may still be maintained by some that tannic acid is a life-saving measure, and that even if it is toxic its use is justified by a general lowering of mortality. But, although mortality from burns has diminished since tannic acid was introduced in 1925, there is no evidence that to-day tanning has any advantage in this respect over other methods.

### ABSORPTION OF IRON

Preservation of the constancy of the internal milieu of the body usually depends either upon a balance between rate of production or absorption of a substance and its rate of usage or elimination (e.g.,  $\text{CO}_2$  tension of blood), or on the existence of a store which can be employed to even out lack of correspondence between rate of absorption and usage (e.g., glycogen). There are but few instances where level is regulated chiefly through control of the rate of absorption. But the recent work of Hahn and his co-workers<sup>11</sup> seems to suggest that the absorption of iron by the gastro-intestinal tract is regulated according to the size of the iron stores of the body. Despite a long-held belief to the contrary, McCance and Widdowson<sup>12</sup> have shown that elimination of iron from the body in the human subject occurs very slowly. A considerable excess of iron may harm those cells in which it is stored—e.g., liver and pancreas cells in haemochromatosis—and the body appears to be guarded against a too liberal intake of iron by the rate of gastro-intestinal absorption. Hahn and his colleagues have studied the uptake and shuttling of the elusive iron in the body in various conditions by following the course of the radio-active isotope after absorption. A known amount of radio-iron is introduced into the gastro-intestinal tract, and the amount circulating later in the red blood corpuscles is determined. In the experiments now reported they confirm their earlier findings<sup>13</sup> that the normal or the plethoric dog with ample reserve stores of iron absorbs very little radio-iron, but that the anaemic dog without stores will absorb 5 to 50%, varying with the amount administered, which promptly appears in new cells in the circulation. Since similar observations have been reported from the same laboratories for the human subject,<sup>14</sup> search has been made for the factors which control the absorption of iron. It has been shown that in dogs rendered acutely anaemic by haemorrhage absorption of radio-iron is within normal limits, but that after a week or a fortnight, when blood regeneration has begun and the iron stores have been depleted, the ability to absorb is increased and may be 5 to 15 times the normal. The means by which the iron reserves can affect the absorbing power of the gastro-intestinal mucosa is not clear; it is not through anoxia which may be consequent upon the anaemia. The giving of a dose of ordinary iron, however, 1 to 6 hours before the radio-iron in the anaemic iron-depleted dog causes a "mucosa block"—that is, the uptake

of radio-iron is less than anticipated. On the other hand, iron administered intravenously does not appear to affect intestinal absorption. The conclusion is tentatively advanced that absorption of iron by the mucosa involves a loose combination of the iron with an acceptor before it is passed on to the plasma. It is suggested that a substance such as ferritin or apoferritin<sup>15</sup> may be responsible. The rate of transfer of iron from the alimentary tract may be governed by the plasma iron concentration. In the normal animal with a normal plasma iron the acceptor mechanism is regarded as physiologically saturated with iron and incapable of picking up more from the gastro-intestinal tract. When the iron reserves are depleted the plasma iron concentration falls and transfer across the gastro-intestinal mucosa is possible.

### ADULT MORTALITY

It has often been pointed out that the improvement in what is called the complete expectation of life during the last century is mainly due to decreases in rates of mortality over the first few years of life. We are, however, still inclined to think that one reason why statesmen of 150 years ago reached Cabinet rank at an age which now would hardly qualify them for minor office was because few survived to be Elder Statesmen. That is a mistake. The circumstances of the country in 1806 seemed almost as grave as those of 1940, and an all-party Government was formed. The Cabinet consisted of eleven members: the eldest was 57, the youngest 26, and the average age 49. The Cabinet Mr. Churchill formed in 1940 was a much larger body, but we can compare the eleven members of his Cabinet holding the same offices (substituting the Secretaries of State for Air and the Dominions for the Lord-Lieutenant of Ireland and the Lord Chief Justice) as the Cabinet Ministers of 1806. The eldest was 67, the youngest 43, the average age 55. Of Lord Grenville's Cabinet only one died under 60; of the remaining ten eight survived 70, and four of these survived 80 years. The English Life Table of 1930-2 would not predict as good results; however, Cabinet Ministers of the early nineteenth century did not come from the general population but from the landed gentry. Indeed only Lord Sidmouth, whose father was Chatham's physician, could be described as of the middle classes, and even of middle-class mortality our knowledge is incomplete. A recent paper by Sir William Elderton and Mr. Ogborn<sup>16</sup> throws some light on the changes in the rates of adult mortality in middle-class males over the last 150 years. In Sir William's own office, the Equitable, there has been a steady improvement even for so advanced an age as 62. Taking the rate for 1763-1829 as 100, that for 1863-93 is 80 and for 1924-8 55. As age advances, the difference between past and present decreases and has disappeared by the age of 82. What may be the "law" of mortality at very advanced ages is unknown. The comparatively scanty exact records of survivorship at ages beyond, say, 90 can be "fitted" by many different "laws," including one which postulates the longevity of Methuselah as not an impossible but only a very rare event. It does appear that sexagenarian juveniles have a greater expectation of survival than had their great-grandfathers.

Dr. Hugh S. Stannus will deliver the Lumleian Lectures before the Royal College of Physicians of London on Tuesday, April 18, and Thursday, April 20, at 4.30 p.m. at the College, Pall Mall East. His subject is "Some Problems in Riboflavin and Allied Deficiencies."

## A MOST EFFICIENT WOUND ANTISEPTIC

'Acramine' Red combines a very high antiseptic action with minimum effect upon the tissues of the host. It is thus a near approach to the ideal antiseptic.

This new compound has significantly less effect upon the tissues than the other aminoacridine antiseptics and thus does not interfere with wound healing. It inhibits growth of all organisms commonly associated with wound infection and particularly it is effective against *Ps. pyocyanea*. It is penetrative and retains activity in the presence of tissue fluids.

Bottles of 25g. and tubes of 1g. of powder.

## 'ACRAMINE' RED

BRAND OF 2:7-DIAMINOACRIDINE HYDROCHLORIDE

GLAXO LABORATORIES LTD., GREENFORD, MIDDX. BYRON 3434

Reproduced from the  
Grand National Release  
"The Stars Look Down"

Purified, decolorised, non-staining  
aromatic, maximum tar effect

A smooth paste, easily applied. The tar component retains the essential phenolic compounds unimpaired, ensuring powerful antiseptic action. All indications for Tar Treatment are indications for "E.S.T.P." (Martindale), more especially infantile eczema; eczema generally, subacute, acute, chronic, moist and dry, with their multiform lesions; impetigo, complicating occupational eczema; prurigo; pruritus; psoriasis; pityriasis circinata; lichen planus. In 2 ozs. and 16 ozs. jars.

FORMULA  
Ether Soluble ... 15%  
Tar Distillate ... 24.5%  
Starch ... 24.5%  
Zinc Oxide ... 14.0%  
In a special emollient base

COAL  
TAR

# ASCABIOL<sup>®</sup>

TRADE MARK

brand of benzyl benzoate emulsion

for the treatment of  
*scabies*

A single application of benzyl benzoate emulsion, provided it is thorough, will usually cure a case of scabies. The chief advantage of benzyl benzoate over some other sarcopticidal agents is the rarity of dermatitis following its use, and recently the formula of 'Ascabiol' has been modified so that skin irritation following its use is minimal.

Pads of instruction cards for patients and a pamphlet are available. Pediculosis Capitis—

Benzyl benzoate destroys lice and, as prescribed in 'Ascabiol' emulsion, also dissolves the cement by which the nits adhere to the hairs. Instead of by the painstaking use of the small-tooth-comb, the nits are removed simply by washing the hair.

'Ascabiol' brand of emulsion contains 25 per cent. benzyl benzoate, and is supplied as follows:—

Bottles of 4 ozs.

Bottles of 80 ozs.

## The Choice of a HYPOCHLORITE

### Why Electrolytic?

"It is possible to obtain a solution even less irritating than Dakin's solution if we prepare it by the electrolytic method. Electrolytic Hypochlorite has not hitherto been employed in surgery on account of defective keeping properties."

Carrel and Dehelly *Military Medical Manuals*, "The Treatment of Infected Wounds," 2nd Edition (1918), p. 24.

### Why Milton?

Because *Milton*, the only stable brand of Electrolytic Sodium Hypochlorite, retains its effective strength for several years; and Because *Milton*, either full strength or in the dilutions commonly employed, is far less alkaline than Dakin's solution of comparable strength.

*Milton* 1 in 20, for example, has a pH of 8.89. *Dakin's solution* 1 in 10 (which

has the same content of available chlorine and hence the same oxidising power) has a pH of 10.64. *Milton* (full strength) has a pH of 10.7. *Dakin's solution* (full strength), which has half the content of available chlorine, has a pH of 11.61.

Because recent work emphasises the lack of irritant action (this is largely due to the absence of free caustic alkali). One surgeon gives as his reason for preferring an electrolytically prepared hypochlorite to a chemically produced solution the fact that after its action is completed only a saline residue remains, "whereas chemically prepared varieties, such as *Dakin's solution*, have more irritant end products."<sup>1</sup> Another states, "*Eusol* for treatment in the wards has been replaced by *Milton* solution in the strength of 1 in 20. This gives an isotonic solution, is quite painless and has the advantage that when its hypochlorite ele-

ment has finished action only normal salts are left. It was found that the boric acid left from *Eusol* tended to make the wounds somewhat painful and slightly boggy."<sup>2</sup>

For blandness, stability, low alkalinity combined with effective proteolytic action and innocuousness of end products the choice is—*Milton*."

**MILTON**, the stable brand of Electrolytic Sodium Hypochlorite, non-caustic and of standard strength (1%)

## DISTRICT NURSING IN LONDON

The annual meeting of the Central Council for District Nursing in London was held on Feb. 24. In the report on the year's work it was mentioned that in some districts within the Metropolitan Police area the proposed new scales of salary for district nurses as recommended by the Rushcliffe Committee would not involve the local associations in much extra expenditure, but for the most part there would be considerably increased outlay, even though the Government would pay, through local authorities, 50% of the increase. It was the hope of the Central Council that the new standard would make it possible for trained nurses to contemplate a career in this vital and interesting work with the knowledge that pay would be reasonably adequate.

Another matter mentioned was that an increased number of applications have recently been received for "analgesic bursaries" which have been offered to enable nurses to receive instruction in the administration of gas-and-air, and the District Associations have found it necessary to make an effort, which was not possible in the more difficult years of the war, to release nurses for the period of the course.

The District Nursing Associations covered by the Central Council number 84, and during 1943 they received from various charities, funds, bequests, and subsidies a total sum of £13,072. The trustees of London Parochial Charities placed at the disposal of the Council £3,500 for distribution. The London County Council, in addition to its contribution of £7,461 for public assistance nursing, continued a grant of £200 for the nursing of the complications of midwifery. District nurses during the year made, under the L.C.C. arrangements, 132,800 visits to 5,478 patients for general nursing, and 103,600 visits to 1,412 diabetic cases for the purpose of insulin administration.

At the conclusion of the meeting of the Central Council Sir Stanley Woodwork, chairman of the Executive Committee, presided at a reception in honour of Sir William J. Collins, who has been chairman of the Central Council for over thirty years. Occasion was taken to mark the sense of respect and affection in which Sir William is held by those associated with nursing, and of admiration for his extraordinary record of service.

## ECONOMY IN THE USE OF DRUGS

The Therapeutic Requirements Committee of the Medical Research Council has made the following amendments in the entries in War Memorandum No. 3:

**Ascorbic Acid.**—Reclassified B (essential for some purposes but not for others; to be used with strict economy); it should be prescribed only in the presence of medical indications for its use; not to be used as a supplement to normal diet.

**Cod-liver Oil.**—Reclassified A (essential or readily available).

**Vitaminized Oil.**—Reclassified B; this preparation is in short supply and should be used only when cod-liver oil is not tolerated.

Speaking at a conference held at the National Institute for the Deaf, in London, Mr. George Tomlinson, Parliamentary Secretary to the Ministry of Labour, appealed to voluntary organizations to co-operate with those responsible for the administration of the Disabled Persons (Employment) Act. Under the interim scheme, which had been in operation for the past two years, many disabled men had, he said, been trained and put on to work which would previously have been regarded as beyond their capacity. To-day 37 different jobs in one particular section of the engineering industry were being undertaken by blind workers. Deafness could be and often was a handicap in obtaining and retaining employment, and persons so handicapped came within the provisions of the Act. They would go to a vocational training centre to be taught a new job, and not only would they be paid while being trained, but those dependent upon them would be looked after. The expenses of training would be defrayed out of moneys provided by Parliament. After training the disabled person would be included in a register of all whose disability was a handicap in obtaining and retaining employment (there would be registration at all local labour exchanges) and an employer of more than 20 persons would be under an obligation to take a percentage or quota of disabled persons. Thus the deaf would be assured of work because the number on the register would determine the percentage required to fill the posts available. Mr. Tomlinson concluded by saying that it would be possible to form a nucleus round which to build the central advisory committee and the local advisory committees to be set up under the Act.

## Reports of Societies

## AETIOLOGY OF INFECTIOUS JAUNDICE

The Section of Experimental Medicine and Therapeutics of the Royal Society of Medicine organized a discussion on March 14 on the aetiology of infectious jaundice. Dr. R. D. LAWRENCE presided.

## Animal and Human Transmission

Dr. F. O. MACCALLUM described recent work recorded in the literature on transmission of infective hepatitis in animals and human beings. The animal experiments were almost wholly negative, but it had been shown that blood in the pre-icteric stage and up to the second day of jaundice was infective for man. The experiments on animal transmission by Findlay, Murgatroyd, and himself yielded negative results on using whole blood, serum, nasal washes, faeces, and urine from pre-icteric and first-day jaundice, and inoculating by all possible routes hedgehogs, rabbits, guinea-pigs, and many other species of animals. Among experiments in human transmission, Cameron in Palestine had reported results indicating that there was an infective agent in the blood from the second day of jaundice, and Vogt, a German worker, had reported several positive results of inoculation into volunteers of duodenal juice, blood serum, and plasma in the pre-icteric stage. In the case of homologous serum jaundice, again, the animal results seemed invariably to be negative, but in man some positive results were recorded. Bauer and himself had taken the serum from seventh-day jaundice and inoculated five volunteers subcutaneously; two of them developed jaundice, and another a rise in bilirubin lasting for about a week.

## Homologous Serum Jaundice

Dr. A. M. MCFARLAN gave a brief sketch of an outbreak of hepatitis after the use of mumps convalescent plasma which had been studied by the Red Cross and Harvard field hospital unit. Jaundice or at least a rise in bilirubin developed in a number of cases after the intravenous injection of the plasma. The picture of the condition in 47 cases admitted to hospital resembled that of infective hepatitis. There were no deaths, and recovery was in all cases complete. When the signs and symptoms were analysed and compared with the findings in 39 cases of ordinary infective hepatitis admitted to the same hospital over roughly the same period one or two striking differences appeared. They are best set out in the following table:

	Plasma hepatitis (47 cases)	Infective hepatitis (39 cases)
	19 per cent.	62 per cent.
Vomiting	.. .. .	.. .. .
Arthralgia	.. .. .	.. .. .
Rash	.. .. .	.. .. .
Enlarged liver	.. .. .	.. .. .
Palpable spleen	.. .. .	.. .. .
Fever, 100° F.	.. .. .	.. .. .

Therefore there were some reasons for thinking that the disease differed a little from ordinary infective hepatitis. The laboratory studies included various examinations which excluded the possibility that it was an outbreak of virus disease. He thought it was clear that icteric batches of serum or plasma did turn up from time to time, but when cases were brought forward as plasma jaundice or homologous serum jaundice every effort should be made to discover, first, whether there were cases of infective hepatitis in contact, and, secondly, the source of the blood or blood products concerned. Without some idea of where the blood came from it was practically impossible to be sure in these cases. Until the aetiological agent was isolated from some of these homologous serum jaundices and from the infective hepatitis cases, or some specific serological test was developed, they would have to go on arguing whether the conditions were the same or different. All he had hoped to do was to furnish something to argue about.

## Post-arphenamine Jaundice

Major J. MARSHALL said that jaundice might occur at any time during the arsenical treatment of syphilis, but there were times when it tended to occur most frequently. There was a possibility of hepatitis within 6 to 15 days after the arsenical injection, and also of a delayed hepatitis about 100 days after

the start of treatment. It was possible for a patient to have both the early and the delayed hepatitis. The early hepatitis varied in severity right up to frank icterus, but it was usually quite mild and transient. The delayed jaundice occurring from the twelfth to the seventeenth week after the beginning of arsenical treatment was the commonest variety. It occurred in any type or stage of syphilis in the adult. Clinically this post-arsphenamine jaundice was indistinguishable from infective hepatitis; biochemically no significant difference between the two had been shown, and the liver changes were said to be the same in both diseases. Post-arsphenamine jaundice varied in severity from the mildest form to a fatal acute yellow atrophy. It was obvious that the arsenic itself had some part in the story, but it might not be the most important factor. The incidence tended to rise in times of economic stress. It varied enormously from clinic to clinic and from command to command. The incidence at the civilian and the R.A.F. clinics was much lower than at the Army clinics in the same area, though the methods used were not materially different. The incidence of jaundice among officers was at least as high as among other ranks, yet in peacetime the counterpart of the officer—namely, the private patient—practically never got this jaundice. The incidence in his own female clinics, civil and military, was well under 5%, yet Service women under his care were treated in exactly the same way as men. The only outstanding difference between post-arsphenamine jaundice and infective hepatitis was that the one had an incubation period of 100 days and the other of 30 days, and the former appeared to be spread by syringe infection. An attack of post-arsphenamine jaundice seemed to offer no immunity against infective hepatitis. The control of the condition was in the proper sterilization of syringes in clinics and in increasing the diet, particularly protein.

Major SALAMAN said that, being convinced that post-arsphenamine jaundice might be spread from patient to patient in clinics by means of syringes, he had inaugurated in his own clinic a scrupulous ritual with regard to syringes, with the result that there had been a significant drop in incidence. The fact that so many of these cases were now being noted was due partly to the shortage of syringes, which made the ordinary methods of using them more dangerous than formerly because they were not allowed to lie long enough in the disinfectant between injections, and partly to the fact that there might be an increase in the number of persons in the population who were healthy carriers or were in the prodromal stage.

#### Yellow Fever Vaccine Jaundice

Col. T. BADGER, U.S.A.M.C., said that epidemic hepatitis in the United States Army made its appearance in the spring and early summer of 1942. Northern Ireland was the centre of nearly all the cases appearing in the United Kingdom, but outbreaks were noticed wherever the troops were stationed. The aetiology was obscure. There appeared to be an association with yellow-fever vaccination, but it could be clearly stated that the jaundice was not yellow fever in any form. Convalescence was slow, but recovery was complete. The mortality was under 1 in 1,000. The number of weeks after yellow-fever inoculation when the jaundice appeared averaged sixteen. The jaundice-producing agent in yellow-fever vaccine was shown to be filterable; it survived drying at 4° C. over long periods, and survived heat at 56° C., and appeared to be neutralized by radiation.

In some further discussion Dr. McLACHLAN mentioned the serum colloidal gold reaction in infective hepatitis and in arsenical jaundice respectively. In a series of 105 cases of infective hepatitis this reaction was positive in 95%, and in 50 cases of arsenical jaundice it was positive in 42%, appearing to indicate some essential difference in liver metabolism. Dr. LOUITT gave grounds for suggesting that the transmission of arsphenamine jaundice was not purely a question of the transference of an infective hepatitis virus from case to case, but of an agent in human serum, whatever it might be, from one person to another. Sir HENRY TIDY recalled two recent developments in the study of jaundice. One of them arose about 1928-30, when catarrhal jaundice, as it was called, in old people attracted attention. The older the patient the longer the clinical course. The other arose about 1935 with the observation that jaundice was comparatively common in

glandular fever, though he himself had for many years noticed an occasional association. This, however, was now so common that he saw in a recent description of glandular fever the setting apart of a definite subgroup, which it was said began with jaundice. He thought there was some tendency to look upon hepatitis, when it occurred, as a single entity, and to neglect lesions in other parts of the body—for example, the kidneys. There was the further question whether in all these cases the same factor was concerned and whether, if it was the same factor, it might be infectious on transmission by one route and not by another.

## Correspondence

### The Effects of Cold

SIR,—Will you allow me to comment upon the papers and correspondence on the cryopathies which have appeared in recent issues of the *Journal*?

In their paper (Feb. 12) Majors Goldstone and Corbett have contributed a most interesting new observation to our rapidly growing knowledge of the effects of cold. The appearance of hepatic and duodenal damage has not been reported before. I think, however, that the difficulty of clinical research on active service far from libraries has led them into certain errors.

It is not "surprising" that they should have observed immersion foot at temperatures above freezing-point. This phenomenon was noticed by Larrey in the Napoleonic wars and by many military surgeons since. I stressed this in a paper which they quote (*Lancet*, 1941, 2, 689—not vol. 1, as stated by them). The explanation is very simple. Water is a good conductor of heat, and if the feet are wet they lose heat rapidly at any environmental temperature below 98° F. If the loss of heat is sufficient to overcome the body's first adaptations, vasoconstriction and consequent ischaemia occur. On the other hand, dry air is a very poor conductor and extreme cold is needed to produce damage in such an environment. It was failure to understand this fact that led to the appalling casualty rate from trench foot and frost-bite in the last war (84,670 cases in the British Army alone). Most of the damage occurred at mild temperatures in France and Flanders.

The actual freezing to hardness of the skin has been overstressed. It is true, as Lake said in 1917 (*Lancet*, 2, 557), that damage tends to be more severe if solidification occurs. I cannot, however, agree with Goldstone and Corbett (Feb. 12) or with Lake (Feb. 26) that it is the essential feature. On the one hand, severe damage, even gangrene, has often been observed (indeed, by Goldstone and Corbett themselves) at temperatures well above the freezing-point of skin. On the other hand, as I pointed out in another paper which they quote (*Lancet*, 1942, 2, 695), solidification can take place without damage. I showed this in the feet of cats, the tails of mice, and (accidentally) my own fingers. Pathologically, there is no clear distinction between "true frost-bite" and "chilling" (Greene, *J. Path. Bact.*, 1943, 55, 259). Clinically, the distinction is slightly greater, but it is only one between acute and subacute disorder. The concept of "mixed forms" is therefore unnecessary.

My friend Mr. Norman Lake remarks (Feb. 26) that "it has, of course, never been suggested that immersion foot bore any relationship to true frost-bite." On the contrary, I have often suggested it and am still unable to understand the grounds for differentiation. With the rest of Mr. Lake's letter I am in enthusiastic agreement.—I am, etc.,

RAYMOND GREENE.

### "Immersion Foot" and Cold Therapy

SIR,—I am indebted to Mr. Norman Lake for drawing our attention to his very important conclusions of nearly 30 years ago. However, I am at a loss to understand why it appeared to him we implied that trench foot and frost-bite were probably synonymous terms. That there has been until comparatively

recently a certain tendency to confusion of these three conditions one with another also cannot be denied.

We were concerned in our article with presenting a conception of aetiology and of confirming to some extent the clinical picture portrayed in the very able article of Ungley and Blackwood. Our suggestion of mild active vasodilatation was based purely upon our conception of the nature of this condition, as opposed to pure frost-bite, and I well recall the relief of pain that resulted from the use of the cradle, particularly in the batch of ten that were observed. They were observed constantly over a period of two months, and gangrene certainly did not occur.

I may add that while I read Mr. Lake's second edition of his book *The Foot* with great interest and benefit, the third edition was unavoidably not available to us at the time of writing our article.—I am, etc.,

H. VINCENT CORBETT.

### Pulmonary Emphysema

SIR,—Recently Christie, in his Goulstonian Lectures, has directed attention to the inadequacy of the pathology of this condition, and I suggest that this is due to the general neglect of the importance of the bronchial circulation. Since Christeller (1916), Lemoine (1936) has written a monograph on the importance of the thrombosis of the bronchial artery as the cause of chronic adult dilatation of the bronchi, although Brenner (1935), in his *Pathology of the Pulmonary Vessels*, alludes to the atonic dilatation of the bronchi in pulmonary emphysema.

At routine necropsy it is the commonplace for the bronchial vascular system to escape notice, as it is an early casualty in the evisceration of the thorax. For this reason it is not remarkable that this portion of the vascular system is not investigated, but it is regrettable that this system of analogous importance to the coronary system should be overlooked in pulmonary disease.

The extent of the bronchial vascular supply is not generally appreciated. In man it is not only the nutritive avenue of the bronchi and intrapulmonary tissues, but supplies the visceral pleura, oesophagus, pre-vertebral muscles, and occasionally the anterior portions of the vertebral bodies. Its intrapulmonary supply is also given to the pulmonary nerve trunks and to the vasa vasorum of the pulmonary vessels (Berry, 1935).

Now, in considering the factors in the development of emphysema, admitting the usual causes of chronic bronchitis and asthma, the first stage is the disruption of the integrity of the bronchial circulation. This is a major factor in the pulmonary blood flow, as it has been shown that the bronchial and pulmonary vascular systems are haemodynamically linked in a capillary bed which is partly common to both (Berry and Daly, 1931). This mainly affects those capillaries which are in contact with the alveoli. It follows that the impairment of the pulmonary tissue secondary to the loss of its proper nutritive channel—the bronchial supply—will permit extensive damage on the stress and strain of coughing on the weakened lungs. The term "hypertrophic" is a pathological misnomer when applied to pulmonary emphysema, as the bulk of the distended lung is due to loss of elasticity and is really "atrophic" when studied histologically.

If we consider the distribution of the bronchial circulation, it can be seen that any diminution in supply to the vasa vasorum of the pulmonary artery will give rise to the atherosclerosis of these vessels to which Christie makes reference. In those cases of emphysema which arise without pre-existing bronchitis or asthma a primary lesion of the bronchial vascular system is responsible (and overlooked). Conversely, the glass-blower or wind instrumentalist is in no danger of emphysema so long as his bronchial circulation is intact.

Clinically, I find the tape measure does not bear any true relation to the degree of dyspnoea. The signs I find of the greatest value are the hyperresonant percussion note and the encroachment of the emphysematous lung on the complementary pleural spaces.

I agree that pulmonary vascular congestion is the true cause of dyspnoea, as shown by its disappearance in those few cases where the pulmonary valve has become incompetent. This similarly happens in mitral stenosis occasionally.

Sufficient has been said for the appreciation of a bronchial vascular lesion as the primary factor in the production of emphysema, with strain or raised intrapulmonary pressure against a closed glottis as the secondary factor. In no way am I seeking to minimize Christie's points, but I would suggest that there is a lot to be said for reversion to the old technique of cadaveric vascular injection prior to investigation of pulmonary disease.—I am, etc.,

BURTON-ON-TRENT.

### Gold Treatment of Arthritis

SIR.—Your leader (March 4, p. 329) commenting on the work of Freyburg, Bloch, and Levy on the use of gold in arthritis is timely and interesting. Their work in 1941 drew attention to the fact that the usual dosage of gold was too high, producing a greater frequency of toxic reaction with no corresponding rise in therapeutic efficiency. This has been appreciated from clinical experience for some time by those interested in these matters, but gold treatment is also used by many practitioners with no great experience.

Freyburg *et al.* in their more recent work have added to knowledge, but still leave something to be said from the clinical angle. Their present view is that 50 mg. of myocrisin (or sanocrisin) weekly is the minimal dose which produces a therapeutic effect with any degree of certainty. This, however, is still high enough to cause toxic reactions (in their case, and under expert guidance, 17%). As a proposition stated in general terms let me hasten to say that this would meet with general approval. Unfortunately this hypothesis will be accepted by the doctor who only uses gold salts occasionally as the whole truth and nothing but the truth. As in so many cases, the real truth is a compromise and could be stated as follows.

There are many cases of infective (or rheumatoid) arthritis which are resistant to gold treatment at any dose less than 50 mg. weekly, but there are also many cases of arthritis which respond to gold treatment at a much lower dosage level. As an example: 400 cases of infective arthritis have been treated over the last 10 years with crystalline salts of gold. Of these about 25% have proved entirely resistant to gold in any dose, and little but disaster has followed increasing the dose over 50 mg. of the salt intramuscularly weekly. Of the remainder about 50% have been found to respond as well with 5 mg. weekly as with 50 mg. The remaining 50% have to be raised to the top dosage to achieve the desired result.

With this experience it can be said with some hope of approximating to the truth that, from the point of view of gold therapy, cases of infective arthritis can be divided into three groups: (a) Those entirely resistant to gold. (b) Those who only respond when the dosage is raised to the ceiling level of 50 mg. of a crystalline salt weekly. (c) Those who respond to gold in the very smallest doses (5 mg. weekly). One further deduction can probably be safely made. Those who respond most satisfactorily to the small doses are those with a low sedimentation rate. This is fortunate, as in my experience it is just these cases which react badly to the larger doses. Although a dose of 5 mg. is not put up by the commercial firms at present, so far as I know, it is quite a simple matter to take half a 10-mg. ampoule, which can always be obtained.

Following the use of this technique only one case of mild dermatitis has occurred in my practice in the latest five years. So far as I can tell, until the cases are statistically analysed the percentage of "symptom-free" patients remains fairly constant.—I am, etc.,

LONDON, W.1.

ERNEST FLETCHER.

### The "Extra Pharmacopoeia"

SIR.—The *Extra Pharmacopoeia* and the *British Pharmaceutical Codex* have established their positions as works of reference so firmly that the attack on them in the review of Volume II of the *Extra Pharmacopoeia* which you published on March 18 cannot pass without a protest from the Pharmaceutical Society.

Your reviewer acknowledges the existence of Volume I. Nevertheless in his search for something to give spice to his criticism he appears to suggest that Volume II stands by itself. Had he studied its contents and compared them with those of Volume I he would have reminded himself that Volume I deals generally with new drugs and advances in medicine and Volume II with the numerous subjects ancillary to those dealt with in the first volume. This division does in fact avoid the "jumble of pharmacognostical information and analytical methods on the one hand with new drugs and advances in medicine on the other" of which he complains. Is it not the duty of a conscientious reviewer to study the contents of the book under review?

Your reviewer is wrong when he says that there is "a lack of connexion" between the Society's Pharmacological Laboratories and its publications; the staff of the laboratories contribute largely to the publications. He is wrong, too, when he complains that the books lack "the benefit of that kind of pharmacological advice which can only be given by those engaged in or trained in research." Leading pharmacologists have ungrudgingly given their help and served as members of revision committees. When he asks, Who is interested in the determination of rotenone in derris? is he not in fact saying, "I am not interested; therefore omit it"? What would his opinion be of the views of any for whom the book fell open at page 171, instead of page 163, and who might deplore the description of methods for the biological assay of digitalis? From his disregard of other sections of this volume of 1,217 pages, dealing with, for example, proprietary medicines, chemotherapy, biological analysis, vitamins, and electrotherapy, one might, perhaps unfairly, conclude that he had not considered it advisable to allow the book to open at any other page.

His determined disregard of Volume I provides him with the grounds upon which he complains of "strange omissions" in the field of new drugs. Let us consider the drugs he names: thiourea and thiouracil have been introduced in this country since the last edition of Volume I was published and will be discussed in the next edition. Pethidine was not known by this name when the last edition of Volume I was published; it was available only in the proprietary form of dolantal. (It was this proprietary form that was the subject of the paper in the *Quarterly Journal* which your reviewer mentions, a paper dealing solely with pharmacology, and not appearing until after Volume I had gone to press.) He has ignored the description of dolantal in Volume I and overlooked the publication of the recent Supplement to Volume I reviewed in your issue of March 11, in which pethidine is included as the name approved by the Medical Research Council for this substance.

A pedestrian review may make dull reading, but it often has the merit of contributing solid suggestions for improvement. Your reviewer might have had less fun, but he would have done better justice to his reputation and that of your esteemed journal had he approached his task with something of the care and pains that have gone into the production of this book over the last four years.—I am, etc.,

HUGH N. LINSTAD, JR.

17, Bloomsbury Square, W.C.1.

of Great Britain.

### How to Break off Alcohol

SIR,—Your issue of March 18 (p. 399) contains an annotation on the so-called conditioned reflex method of treating alcoholics. The underlying idea of associating various drinks with violent nausea originally was given a very elaborate setting or ritual by Voegelin. This ritual subsequently has been modified, but the results obtained are, in my opinion, due to suggestion rather than to conditioning. The number of repetitions is far too small to establish a conditioned reflex, and, as with all forms of treatment for alcoholism, the good will of the patient himself remains essential.

Emetine and apomorphine, apart from their emetic effects, are drugs of long-standing reputation in the treatment of alcoholism and other addictions. Their drastic exhibition reinforced by powerful suggestion does not, in my experience, establish a conditioned reflex, though their administration in this way is so highly disagreeable as to make the risk of a repetition worth while avoiding.

So far so good, but there is a subtle danger in all such violent methods, even when, superficially, they appear successful. Alcoholism must be regarded as a symptom, and its suppression by so-called conditioned reflex methods while its cause remains untreated is a temptation which should be understood and scrupulously avoided. Unless the predisposition of the addict is recognized and treated, he, although possibly eschewing alcohol, will resort to some other method of side-stepping his difficulties. Many alcoholists, particularly doctors, who try to cure themselves thus become polynarcomaniaes.

Apart from recourse to other drugs there are many ways in which the psychologically untreated addict may show that merely "to break off alcohol" is to bring on something else—another and possibly a worse symptom. To warn the unwary against stumbling into this pitfall is my excuse for trespassing upon your valuable space.—I am, etc.,

Caldecote.

A. E. CARVER.

### Effect of Pregnancy and Parturition on Pulmonary Tuberculosis

SIR,—In his interesting review of 100 cases (Dec. 18, 1943, p. 775) and subsequent letter (Feb. 5, p. 196) Dr. Cohen blends cautious comment with precipitate deductions, and in the interests of the tuberculous woman some warning must be given against the acceptance of his "conclusions" without fuller analysis. They were: (1) Pregnancy and labour *per se* rarely exert any harmful effect on the progress of a woman known to have suffered from pulmonary tuberculosis. (2) It follows that therapeutic abortion is not a procedure to be resorted to simply because a woman is known to have suffered from pulmonary tuberculosis. (3) Active pulmonary disease is seldom accelerated by pregnancy and labour, and I have found that in such cases, treated under favourable conditions, pregnancy has been little more than an incident in their tuberculous career.

It should be noted, therefore, that, by accident or design, the Essex arrangements (as described from 1937 onwards) adhere closely to one section of a more extensive scheme which was advocated at a special discussion on this subject during the B.M.A. Conference at Oxford in 1936, when "minimal harm" cases (now brought forward by Dr. Cohen) were already acknowledged, and when practical problems were investigated for giving a greater number of pregnant tuberculous women this degree of advantage over their previous possibilities. An overwhelming weight of evidence was produced at that conference to prove the ever-present dangers of pregnancy for the tuberculous woman, and hence the aim of the Oxford scheme was to counteract these dangers in every possible way by the fullest co-operation between obstetricians and tuberculosis workers. The good results in Essex indicate the value of such a scheme, but, nevertheless, a danger does not cease to exist merely because it is brought within a certain degree of control, and I feel strongly that it would be an unnecessary risk for the patient if we were now to accept the first and third "conclusions" of Dr. Cohen of Black Notley rather than the considered opinions given at Oxford in 1936 by, among others, Prof. Cohen of Liverpool.

Further, Dr. Cohen's deductions are not supported by the latest work elsewhere. It cannot be granted that the supervision and treatment of the tuberculous woman are in any way less in the London area than in Essex; in fact, this must be a material understatement of London's facilities! It may therefore be of interest to make it clear that, to many who have specialized in the care of tuberculous women in London during the last 20 years, the following facts stand out prominently:

(1) In numerous cases the "onset" of pulmonary tuberculosis can be ascribed definitely to the period of a pregnancy; hence pregnancy must retain its place as a prominent precipitating factor in the development of the disease.

(2) In no case can it be shown that a pregnancy has brought about any permanent benefit to the lungs of the tuberculous woman.

(3) A proportion of cases of inactive pulmonary tuberculosis manifest little, if any, harm from a single pregnancy, but this group mainly consists of cases where the disease has been arrested for at least two years, and, even in them, subsequent pregnancies are prejudicial.

(4) The large majority of "active" lung cases tend to deteriorate appreciably during the pregnancy or within a few weeks after labour.

while with bilateral disease the retrogression is out of proportion to the degree of earlier involvement.

(5) To achieve the minimum of ill effect it is essential that combined obstetrical and tuberculosis treatment (preferably under sanatorium conditions) be provided for the tuberculous woman as soon as the pregnancy is detected, that the confinement should be made as "easy" for her as possible, and that intensive tuberculosis treatment should be continued for several months following labour.

(6) While therapeutic abortion is not undertaken as a "routine," in certain cases it is essential for safeguarding the patient's life; but from the tuberculosis standpoint, it can on no account be attempted, without still greater risk to the woman, after the sixteenth week.

It is not within the scope of this letter to amplify the individual points (which are not incompatible with the Essex results) nor to discuss special measures adopted for improving the outlook for both woman and child. But these findings definitely preclude the acceptance of Dr. Cohen's first and third conclusions, while somewhat elaborating his second.—I am, etc.,

Grove Park Hospital, S.E.12.

M. H. LOGG, M.D.

### Shock Treatment of Mental Disorder

SIR.—The true reason for the controversy about shock therapy in mental disorders (Dec. 25, p. 829, and Jan. 8, p. 60) seems to be that this new therapeutic approach undermines certain basic psychiatric concepts. Personal experience with electric shock therapy in almost 2,000 patients in two New York hospitals, suggests an answer to some of the questions brought up in the correspondence. Comparison of results in acute psychotics in an institution and in a second series of voluntary patients offered valuable information on the question shock therapy and/or psychological treatment.

Shock therapy is mainly indicated and is self-sufficient in acute psychoses. In my institutional material no psychotherapy of any kind during or after electric shock therapy was applied; the results were surprisingly good. On the other hand, the patients of the non-institutional group, consisting of borderline cases between neurosis and psychosis, were usually subjected to psychotherapy during and after electric shock therapy. The results were poor.

It is the dramatic symptoms of the psychoses which are accessible to shock therapy but not to psychotherapy. On the other hand, neuroses as well as borderline cases between neurosis and psychosis do poorly under shock therapy. Thus the two therapeutic approaches seem to have quite a different field of application. Dr. Shepley is right in saying that convulsive therapy also promotes accessibility to a later psychotherapy, but this is an application of secondary importance. The types of illness that respond to shock therapy most convincingly do not yield to psychotherapy during the psychosis, and in our experience do not need it afterwards.

It is certainly more satisfactory and appeals more to our intellectual needs to treat with psychological means than to press the button of an electrical machine. No one who has seen the predictable spectacular results in depressions and catatonic stupors or excitements will object to convulsive therapy. But it is disappointing for us to see such results with a method which we are still completely unable to understand. The great progress made in a group of patients where we were helpless before should give us satisfaction as physicians, even though it interferes with the concept of mental illness as a psychologically determined and, therefore, psychologically treatable disease. It should reopen the question of the process underlying mental illness. Our attitude should be not to object to a method because it is empirical, but to use the empirical knowledge for a new scientific approach to the basic problems of psychiatry.—I am, etc.,

New York.

LOTHAR B. KALINOWSKY.

### Acute Respiratory Conditions in African Soldiers

SIR.—Lieut.-Col. W. W. MacNaught and Major Murray-Lyon have drawn attention to such an important problem in their article on acute respiratory infections in Africans (Sept. 11, 1943, p. 324) that it should not go without support from others who have shared their experience.

During almost the same nine months to which they refer, but on the other side of the continent, a large hospital for East

African soldiers admitted 2,071 cases eventually diagnosed as "pneumonia," placing this condition second only to dysentery as a cause of medical admissions. But the case mortality of pneumonia in this hospital was more than double that in the West African series, and in nine months 85 patients died. In fact, many more patients died from pneumonia than from any other group of diseases in the medical wards, and this in spite of the rapid response to sulphapyridine shown by the majority of patients.

The following two observations in support and amplification of the West African experience are put forward as the result of post-mortem examinations upon 83 Africans who died of pneumonia. (a) Upper lobe involvement was common; the right upper lobe was affected in 52 cases and the left upper lobe in 31. (b) A large proportion of the deaths occurred either very early or very late in the disease. In the former the picture was that of septicaemia with minimal lung changes. In the latter there appeared to be a delay of resolution in the areas first affected, so that these lobes remained in a solid, cheese-like condition, while successive involvement of other lobes gradually reduced the remaining available air space. These latter cases had generally proved resistant to sulphapyridine, and one is led to suggest that lack of resolution may have been partly mechanical (the African dislikes moving his chest when ill) and partly due to a damaged lymphatic system, which, no doubt, had been previously visited by many nematode larvae in transit.

It is of interest that the second most potent cause of death in the East African hospital in these nine months was cerebrospinal fever (35 deaths)—another "European" disease—adding weight to the authors' contention that familiar diseases should not be neglected in the Tropics.

In the same article there is an implied criticism of our lecturers in tropical medicine, in that they do not stress the importance of respiratory infections in black troops. It is true they do (or did) not, but they may be excused if they assume that we who are sent to the Tropics go with a working knowledge of European diseases. If under a tropical sun we lose our perspective in medicine it is not their fault; yet that perspective is only too often lost, and Lieut.-Col. MacNaught and Major Murray-Lyon do well to attempt to restore it.—I am, etc.,

A. B. RAPER,  
Major, R.A.M.C.

### Tonsillectomy in Children

SIR.—Mr. T. B. Layton is often original and always dogmatic, but on the occasion of his letter in the *Journal* of March 11 he eclipsed his previous best. Some twenty years ago I remember the late Mark Hovell addressing the Section of Laryngology at the R.S.M. and there advocating that a portion of the tonsil should always be left; the suggestion was rejected unanimously. Even so, history repeats itself, and here we have the hydra-head raised again.

For years I had perforce to remove pieces of tonsil left behind by my colleagues, and some, I regret to say, of my own. To-day I felt that at last, as a specialty, we knew how to remove tonsils. No, I hope my friend Mr. Layton will stick to his own motto: "The tonsil, all the tonsil, and nothing but the tonsil," or a useful paraphrase, "All or nothing." Remove the whole tonsil or leave it alone, and this includes treatment by diathermy, caustic paste, and cauterization. In view of his recommendation to leave a small portion of the tonsil behind, I am not surprised at his evident reluctance to undertake the operation.

The letter of Mr. Carew-Shaw was sane and well balanced. I know of no operation which, when properly carried out in suitable cases, has a greater value to a child—both physically and mentally—a fact which is well recognized by parents themselves.

I am in agreement with Mr. Layton that a careful examination should first be undertaken. I would make the constructive suggestion that this examination should always include the antra; and where the antra are found to be dull they should be washed out. A persistent antral infection in children is often the cause of colds and infections following an otherwise successful operation.

The operation is not to be undertaken lightly or inadvicably, but only after due consideration, and with skill, care, and

gentleness, while mental shock must at all costs be avoided. When so carried out the operation is of great value in promoting the health of the rising generation.—I am, etc.,

Birmingham.

MUSGRAVE WOODMAN.

SIR,—We entirely agree with the views expressed by Mr. T. B. Layton in his recent letter regarding the question of tonsillectomy in children. He states that "no such administration has as yet been set up which will give that minimum of a quarter of an hour between the parent upon whom the responsibility for decision rests and the surgeon in whose hands the responsibility for advising the operation is finally put." We think it might be of interest to him to know that such an administration was initiated in a general hospital eighteen months ago. Here cases may be reviewed weekly or monthly by a team of workers whose aim is a fuller comprehension of the functional efficiency of the entire respiratory tract, with an attempt at classification of "criteria" whereby the operation of tonsillo-adenoidectomy may be considered justifiable and good results reasonably expected.—We are, etc.,

F. C. W. CAPPS.  
E. GWYNNE-EVANS.

Willesden General Hospital.

### Infiltration of Oxygen for Gas Gangrene

SIR,—Over ten years ago I made short notes of the treatment and progress of a case of gas gangrene which occurred in a hospital where I was a house-surgeon. I lost the notes soon after, but came across them recently and give them below in detail.

On Aug. 28, 1933, a well-built man of 43 years was admitted to hospital following a road accident. He had sustained a compound fracture of the right ulna in its upper third, the wound being on the posterior aspect of the arm, and a lacerated wound of the right antecubital fossa. He had no other injuries. Under gas-oxygen and ether anaesthesia the fragments of the ulna were brought into alignment, the wounds loosely sutured, and small drainage tubes put in position. Antitetanus serum was given.

On the afternoon of Aug. 29 the patient's temperature shot up to 103° F. and his pulse rose to 90. On the following morning the right upper arm in its lower third and the right elbow region were found to be brownish red in colour, swollen and painful, and from the wounds there was oozing a dark foul-smelling discharge. Anti-gas-gangrene serum was given—all we held ourselves and some borrowed from another hospital, a total of 20 c.cm. The surgeon in charge of the case opened the wounds extensively, made multiple incisions in the infected area, and freely applied hydrogen peroxide. The surgeon, in consultation with his colleagues, decided against amputation because of the rapid spread of infection and the attendant deterioration in the patient's general condition.

By the afternoon of Aug. 30 it was distressingly obvious that the treatment was going to be of no avail. By evening the infection had spread up the arm to involve the pectoral and upper scapular muscles. Crepitus was easily palpable throughout the affected area. The patient was restless and anxious and the prognosis could not have been worse. The senior house-surgeon, Dr. D. M. Mackechnie, decided to try the effect of pure oxygen on the infected tissues. An ordinary intravenous needle was fixed to the end of a thin rubber tube, the other end of which was attached to the outlet valve of an oxygen cylinder. I got the patient under ether anaesthesia while my colleague thoroughly infiltrated with oxygen the whole of the upper arm and the affected areas on the chest and shoulder. Oxygen was also injected into apparently still healthy tissues ahead of the advancing and well-marked line of demarcation. The existent swelling was accentuated by the blowing up of the tissue with oxygen.

On the morning of Aug. 31 we could hardly believe our eyes. The skin over the chest and shoulder was practically normal in colour, while on the upper arm it had improved considerably in appearance; obvious swelling had gone from the shoulder and chest and was subsiding in the arm. There was no tenderness on pressure on the chest and shoulder and very little discomfort in the arm. Round the elbow-joint there was no change in appearance and swelling, though the stench did not seem to be so overpowering as previously. There was still some crepitus here and there in the chest, shoulder, and arm, but whether from oxygen or anaerobic action it was impossible to say.

The improvement, local and general, was as dramatic as had been the onset and spread of the gangrene. On Sept. 1 the surgeon amputated the arm slightly above mid-humerus. No attempt was made to form a flap or to trim the stump, which was loosely covered with dressings soaked in hydrogen peroxide. Two or three days later the bone stump was trimmed and a flap fashioned. The patient made an uneventful recovery thereafter.

It seems to me that the use of oxygen as described above in the treatment of gas gangrene is reasonable and logical, though I personally would not have thought of getting at the anaerobes in a manner which proved so devastating to them. The anti-gas-gangrene serum given and the recognized surgical measures taken as soon as gas gangrene was suspected did nothing to arrest the alarming spread of the infection. On the other hand, it proved beyond any shadow of doubt to all those concerned with this case, that the gas gangrene was not only arrested but cleared from heavily infected tissues by the intramuscular administration of oxygen.

One cannot, of course, suggest that all other cases of gas gangrene would react so dramatically and so satisfactorily to the same treatment. During the past ten years I have frequently described this case to professional colleagues. Some listened with apparent interest, others with obvious disbelief. Now, it may be that this method of treating gas gangrene has been tried out by others, but I have never read of it, nor have I met any medical man who has heard of its having been used.—I am, etc.,

N. M. MACDONALD,  
R.A.F.V.R.

### Cause of Silicosis

SIR,—In letters appearing in the *Journal* (1937, 1, 195, 474) I gave hypothetical reasons and suggested *modus operandi* permitting a conclusion that the cause of silicosis might be physical in a mechanical sense rather than chemical; in short, involving the laceration of pulmonary tissue as a result of the sharpness of the particles inhaled.

Recently indirect evidence (Cantor Lecture, Royal Society of Arts, 1943) has been forthcoming which appears to support such a mechanical causation—namely, the work of H. V. A. Briseoe and others indicating that the destruction of weevils by inorganic dust is due to the physical characteristics of sharpness and relative smallness of the particles. There appears to be a clear identity in the two cases—(a) human lungs and (b) weevils—as regards the *modus operandi* of sharp particles. This identity is: continued movement of the respective tissues relative to and under the sharp particles continuously present. It is known that such movement exists in the human lung both before and after arriving particles have lost their own momentum. It seems probable there is continued subparticle movement of cuticle in the case of weevils. This probable identity is extremely significant as indicating the possible mechanical cause of silicosis. While the laceration consequent on the weevil cuticle being drawn to and fro under numerous cutting points would explain certain data in the case of weevils, in the case of silicosis such parallel lacerations in the human lung might readily admit the finest particles with certain (possibly chemical) reactions as effects of the mechanical cause of silicosis.—I am, etc.,

S. C. BLACKTIN.

### Service Medicine?

SIR,—The enclosed extracts from a letter I have received from a colleague in the Forces so accurately express the views of many serving members of our profession that I feel it should receive wider publicity. I would be grateful, therefore, if you would find room for them in the *Journal*, as we doctors here would prefer them to be published in your paper.—I am, etc.,

J. A. VALENTINE.

\*\* The extracts, after some further abridgment, are printed below:

"... The first premise to what I want to say is so important as to be almost the foreground of the picture: It is that the civil 'front' carries far heavier burdens in feeding, comfort, transport, and relaxation (especially alcohol) than the Services, inasmuch as I have seen them, and yet is far worse off for doctors. This is bureaucracy's passion for over-staffing. Here, for 500 beds (and we have never yet had 300 occupied), there are 15 doctors (not all fit to practise, of course). True, we have out-patient work to do; true, we might have had heavy casualties, necessitating 48 hours' work on end, perhaps; true, it is the Tropics and lethargy is rife. But I doubt if any of us does more than two afternoons per week, most are ready to go home by 12.30 p.m. (we start at 9.30 a.m.), and I am almost certain that one man has never left the hospital later than 12.30 p.m. in 18 months. Another leaves at 12.45 p.m. regularly

nd writes his private letters in his office during the morning. For  
ae, work has increased, but my average attendance per day for the  
months ended Aug. 31, 1943, beat my previous records and yet  
did not reach 4 patients a day.

"So much for over-staffing. Now about bad staffing. In this  
rea there are two men with M.D., M.R.C.P., yet our medical  
specialist is a G.P. and admits freely that he is not up to the level  
of consultant work. Elsewhere there is a specialist in another branch  
(not medicine nor mine) with 15 years' experience on his honorary  
staff at home; the man who practises this specialty in the hospital  
is painfully ignorant, and even I can teach him his job in respect  
of something that he claims to know and I need not. In fact, his  
reports are a waste of good paper. But the other man is not  
appointed to practise his specialty, and so he gets none of the one  
thing he really can do. And that has been so for 18 months.

"This is the background against which to see my attitude to the  
idea of a State Medical Service. I have seen too much of a bureau-  
cracy in medicine in the last 44 years to have any hope of respecting  
the body that, because it pays me, claims to direct my treatment  
of patients. I am convinced that a State Medical Service will lead  
to precisely the same difficulties in the course of time that jirk the  
genuine doctor who happens to be in the Services. These 44 years  
have shown me that bureaucracy puts importance first on paper-  
work, next on the staff, and last of all on the patient. It has been  
said that 'it does not matter if a patient dies so long as he dies in  
red ink.'

"Here is a fact which, to my mind, typifies the complete  
antagonism of a bureaucracy to the system of apprenticeship—which  
has always been, and fundamentally still is, the real high-light of  
medical training. Every C.O. (even if it is only an executive officer)  
renders confidential reports on his officers, even the doctors; bad  
reports must be shown to the officer concerned. But a medium  
report, or a good one, or one that 'damns with faint praise' must  
not be so shown. So it boils down to, 'Never encourage your  
juniors.' How false to the whole atmosphere of training in the  
learned professions! And how true to the type that knows, as the  
lower civil servant does, that his authority is not from within and  
by virtue of professional respect but from without, like a uniform  
bought from a tailor. This fear of encouraging the junior extends  
to almost active attempts to stop the research-minded from further  
progress. It is markedly helped by the passion for 'put it on paper  
and submit it properly,' and further aided by the distance that  
exists between the controlling power and the patient. This distance  
is less geographical than spiritual. The men who 'run' the politics  
of civilian medicine are in touch with doctors who work and/or the  
patient; of the men who run a bureaucratic medicine few would  
know at which end of the patient to start!

"And from my own personal experience I can substantiate the  
things I have said here. Of equipment, the less said the better;  
you know my views, and in a S.M.S. we shall certainly have  
to indent in duplicate and wait a month to get a new Graefe  
knife, and we shall have to prove that the old one is unserviceable.  
I still have a pitiful supply of apparatus, surgical instruments, and  
even sutures, and the authorities do nothing, so I have to use my  
own and even to buy fresh for myself; this after 18 months. I  
protest vigorously (but who can hear my protests?) against the  
reorganization, nay re-creation, of medicine while the vast majority  
of those whom it will affect chiefly are muzzled in the Services.

"Lastly, is not medicine now more advanced towards the com-  
munity ideal of service for others than any other section of the  
community? Can any other section show such a degree of pro-  
gressive spirit and such an amount of progress made towards ser-  
vice as medicine? I think not. But because we are the most  
easily browbeaten, the busiest, and the least organized, we have to  
be the 'Aunt Sally.' How I sigh to be back home again and  
enmeshed in the worries (but worth-while worries) of civil practice!  
Here it's petty politics, lobbying, back-scratching, and form-filling  
all day long."

### India's Population Problems

Sir.—Before deciding that the medical profession should  
advocate the extension of birth control in India as a contribu-  
tion towards an improvement in the living conditions it is  
essential to decide what are the economic factors producing  
the extreme poverty and danger of famine under which the  
masses live. It is saddening to see in the correspondence on  
this subject so many supporters of the Malthusian doctrine  
that increase in population tends to outrun the food supply.  
Prof. Blacklock concluded his article by giving support to this  
belief. Although he mentioned that Henry George emphatically  
denied the theory, yet by a misinterpretation of a statement  
by George he claimed that the great economist was in doubt  
as to the effect of an increase in population. To anyone who  
has carefully read George's book *Progress and Poverty* it must  
be obvious that he was convinced that increase in population

not only does not lessen but, in fact, increases the average  
wealth per head; indeed, so clear and logical are his interpreta-  
tions of the known facts that it is impossible not to be  
convinced of their correctness. Wealth in any form is equivalent  
to food, since it can be exchanged for this commodity on the  
world's markets. It follows logically that the greater the  
population the more remote should be the danger of poverty  
and famine.

The essential condition is access to the gifts of Nature,  
embraced in the term "land," without which no wealth can  
be produced. Under the present well-nigh universal system  
of land monopoly this access is denied or is granted only on  
payment of such a toll in rent as leaves the actual producer  
the bare minimum for subsistence. Under these conditions no  
reserve of wealth can be built up by the labourer, and in  
countries such as India a bad harvest must therefore result in  
famine, unless there is an organized distribution of food at  
the expense of others. In this country the same system pro-  
duces recurrent industrial depressions with millions of unem-  
ployed, who would starve unless maintained at the expense  
of others.

The discovery and proof by George of the cause of these  
evils and their remedy by the taxation of land values is, in  
the science of economics, as important as the discovery of  
the bacterial cause of disease by Pasteur was in medicine.  
It has met with unscientific criticism similar to that with which  
Pasteur's work was greeted, and unfortunately is even now  
recognized only by a small minority of people, although in  
the 60 years since its publication no valid objections have been  
forthcoming. Economics is still treated as an art rather than  
as the exact science which Henry George showed it to be,  
and such measures as the regulation of the rate of reproduction  
as a solution for the evils of poverty, unemployment, and  
famine are akin to the philosopher's stone in that they are  
based on beliefs which have been proved false. They are  
therefore as likely to be successful as was the search of the  
alchemists.—I am, etc.,

St. Andrews, Fife.

H. A. HANTON.

### Consultant and Specialist Services

Sir.—We find ourselves in sympathy with Mr. Hamilton  
Bailey and with Mr. H. J. McCurrich in their distrust of the  
uncertain and dimly lit path which is apparently being prepared  
by the Royal Colleges for the consultant and specialist. The  
light shed on it by the Presidents in your issue of Jan. 15  
was but a fitful flicker, serving only to perplex and mystify  
those of the profession who, like ourselves, are not at present  
in touch with what might be termed "medical politics." Glimpses of mysterious comings and goings, of esoteric meetings  
and plannings, are vouchsafed to us from time to time, but  
serve only to increase our unease.

With all respect, Sir, may we suggest that the Royal Colleges  
are not the most suitable bodies to deal with the question?  
We venture to doubt if they indeed possess the necessary  
statutory power to draw up standards for, and to prepare a  
register of, consultants (which seems to be the object ultimately  
to be attained). The General Medical Council presumably has  
such power, is representative of all professional interests, and  
is universally respected as an entirely fair and unprejudiced  
body. If a register of consultants and specialists is to be  
prepared, and criteria laid down to be fulfilled by those who  
in future wish to take up such work, we submit that the General  
Medical Council is ideally fitted for the task, and is, indeed,  
the only proper tribunal to undertake it.—We are, etc.,

J. R. FORBES, M.D., M.R.C.P.  
Surgeon Lieut.-Cmdr., R.N.V.R.

H. R. I. WOLFE, F.R.C.S.  
Surgeon Lieut.-Cmdr., R.N.V.R.

### Intelligence and Season of Conception

Sir.—The following objection to Surg. Cmdr. Fraser Roberts's  
arguments (March 4, p. 320) seems to me to be a fatal one.  
Intelligence is by no means the only quality alleged by Fitt  
and others to vary with the season of conception. On the  
contrary, to quote from your own columns (Sept. 5, 1942,  
p. 284): "Those conceived during the period autumn-winter  
are on the average slightly taller, heavier, stronger in hand-grip.

and more intelligent than their fellows, as well as *less likely to die during the first month of neonatal life*" (my italics). Hence Fraser Roberts must show either that high intelligence is usually combined with exceptionally good physique or else that good physique also, and independently of intelligence, leads its possessors to beget children in autumn and winter.

Meanwhile those intelligent and well-informed people who want to have big, strong, intelligent children (and who are prepared to put up with the hearty handshakes) will continue to try to beget them between August and January.

It may be worth while to note in passing that if, after all, it is the season that influences intelligence, then, as this information becomes moderately accessible, intelligent people will be the ones to apply it. They will thus make their hereditarily intelligent offspring even more intelligent, and so, secondarily, intelligence will influence the season too. There will in fact be a "virtuous circle."—I am, etc.,

Medical School, London Hospital;

W. J. PENMAN.

## Obituary

SIR DAVID PRAIN, C.M.G., C.I.E.,  
LL.D., M.B., F.R.S., Lieut.-Col., I.M.S. (ret.)

We regret to record the death on March 16, at Whyteleafe, Surrey, of Sir David Prain, the eminent botanist.

Born in Scotland on July 11, 1857, David Prain was educated at the Parish School, Fettercairn, the Grammar School, Aberdeen, and the Universities of Aberdeen and Edinburgh, where he took the degrees of M.A., M.B., and C.M. After acting as demonstrator of anatomy in the College of Surgeons, Edinburgh, and at Aberdeen University, he entered the Indian Medical Service in 1884, and three years later was appointed curator of the Calcutta Herbarium, succeeding Sir George King in 1898 as superintendent of the Royal Botanic Garden, Calcutta, and director of the Botanical Survey of India. From 1887 onwards during his service in India, Prain published a constant stream of scientific papers, mostly botanical, with a few on other subjects, such as his articles on the Angami Naga tribe, the hot springs of the Namba Forest in Upper Assam, and the fauna of Narcondam and Barren Island. His methods and foresight are illustrated by the somewhat unusual way in which he distributed his reprints: instead of sending these out separately, he retained them for a series of years, finally issuing them in two volumes, *Memoirs and Memoranda* (1894) and *Botanical Notes and Papers* (1901). These included papers on the floras of the Andaman, Nicobar, and Laccadive Islands, and on the races of wheat and the mustards cultivated in Bengal, in addition to many descriptions of new plants and revisions of genera. From 1895 to 1905 he was professor of botany at the Medical College, Calcutta, and he was also a trustee of the Indian Museum (1898-1907) and secretary of the Board of Scientific Advice for India (1903-4). The honour of C.I.E., conferred on him in 1906, was a fitting recognition of his services to Indian science in general and to botany in particular.

The second period of Prain's career coincided with his term of office as director of the Royal Botanic Gardens, Kew (1905-22), where he added to his reputation as a prudent and successful administrator, receiving the C.M.G. and a knighthood in 1912. Though his official duties left him but little leisure, he was able to continue his botanical researches, among which may be mentioned an account of part of the large and difficult family Euphorbiaceae for the *Flora of Tropical Africa*. During his period he served on the councils of numerous scientific societies and institutions, including the Linnean Society (president, 1916-19), Royal Society (treasurer, 1919-21), and John Innes Horticultural Institution (chairman, 1904-34), and was president of the Association of Economic Biologists (1919-21).

His retirement from Kew in 1922, at the age of 65, meant for Prain merely a change of work. He became successively director of Forest Products Research (1922-5), chairman, Animal and Plant Products, Imperial Institute (1926-35), and reasurer of the Ray Society (1932-5). The wide range of his interests was reflected in his presidencies of the Gilbert White Fellowship (1921-4), Imperial Botanical Conference (1924),

Quekett Microscopical Club (1925-7), and Essex Field Club (1930-3). Perhaps the most important botanical publication of his later years was a monograph on the Asiatic species of yam (*Dioscorea*), prepared in collaboration with Mr. I. H. Burkill.

Among the honours conferred on Prain were the Barclay Medal of the Asiatic Society of Bengal (1909), the Linnean Medal (1935), the Albert Medal of the Royal Society of Arts (1925), and the Victoria and the Veitch Medals awarded to him by the Royal Horticultural Society (1912 and 1932).

H.H. THE MAHARAJA OF GONDAL, G.C.S.I., G.C.I.E.,  
LL.D., D.C.L., M.D., F.R.C.P.Ed.

His Highness Bhagvat Sinhjee, Maharaja of Gondal, who has died in Bombay, was one of the most remarkable men in India. He was born on Oct. 24, 1865, son of Thakore Saheb Sagramji of Gondal, had his early education at the Rajkumar College, Rajkot, and was elected a Fellow of the University of Bombay in 1885; then he risked the loss of caste and kingdom by crossing the sea to study medicine at the University of Edinburgh. He graduated M.B., C.M. in 1892; in 1895 he proceeded to the M.D. and was elected F.R.C.P.Ed. In recognition of his intellectual gifts, his wide learning, and his services to the State over which he ruled the Maharaja received the honorary degrees of D.C.L. from Oxford and LL.D. from Edinburgh, and the Royal Society of Edinburgh elected him a Fellow in 1909; he was also a member of the Royal Astronomical Society and of other learned bodies in Great Britain and Ireland. Soon after his accession in 1885 he abolished all taxes in Gondal, and that State, which is the healthiest as well as one of the best ruled in India, has been run largely on the revenue of the railways built by him. In 1935 he followed the old Rajput custom of celebrating his jubilee by giving away his own weight in gold to charities. His publications included the *Journal of a Visit to England*, a *Short History of Aryan Medical Science*, published in 1895 and dedicated to his teacher Sir William Turner "in cherished remembrance," and a two-million-word dictionary of the Gujarati language, which took him 10 years to compile. The Maharaja was created K.C.I.E. in 1887, G.C.I.E. in 1897, and G.C.S.I. in 1937.

F. L. ANGIOR, O.B.E., M.R.C.S.

Dr. Frederick Leigh Angior of Wigan died in Stanley Hospital, Liverpool, on March 14, at the age of 74. He was born and educated in Liverpool, and after qualifying in 1896 joined his elder brother in practice at Wigan 48 years ago. Dr. Angior was elected a member of the B.M.A. in 1898 and took a very active part in the local work of the Association, serving for several long periods as hon. secretary of the Wigan Division and as chairman in 1929-30. He received the O.B.E. for the manner in which he carried out the duties of senior medical officer to the Wigan Division of the British Red Cross Society during the last war.

A colleague and personal friend writes:

The death of Dr. F. L. Angior brings to an end the long period of self-imposed and self-sacrificing service which he rendered on behalf of his fellow practitioners in all medical affairs in the Wigan area. For over thirty years he had been secretary of the Wigan Panel Committee and for over twenty-five years he was the honorary secretary of the local Division of the British Medical Association. He had served on the Wigan and Lancashire Insurance Committees and was secretary of the Local Medical War Committee.

Dr. Angior was of commanding appearance, always well groomed with an old-world charm of manner and an urbanity and kindness of nature that made him the ideal person to undertake the various honorary duties he so ably performed. He attended his many meetings regularly and punctually, and even his holidays were chosen to coincide with the Annual Representative Meetings of the British Medical Association. By his assiduous attention to the details of the work he acquired a store of knowledge on all matters relating to the profession and was ever able, and willing, to help, from his ripe experience, any practitioner who desired advice or information. He was always accessible, ever friendly, and endowed with a keen sense of humour, while his hearty and infectious laugh made everyone feel at home with him. His broad sympathies, his tact, wide culture, and profound knowledge of human nature helped, in great measure, to bring about a happy and contented brotherhood in Wigan, where for years the practitioners have worked in harmony.

Dr. Angior's sense of duty was high. He was aware for some time that he was a very sick man, and, without doubt, had not the

present war arisen, with its increased work and responsibilities, he would have taken the time to have his condition investigated at an earlier date than he ultimately did. He chose, however, to work on, and died practically in harness, leaving a sense of deep loss in the hearts of his colleagues, who, one and all, feel the sincerest sympathy for his elder brother, Dr. T. M. Angior, with whom he has worked in happy partnership for nearly fifty years. Almost all Dr. Angior's time in recent years was given to his professional duties and honorary appointments, but he had a life-long interest in music and dramatic art. He was a Freemason of many years' standing. In his daily life Dr. Angior embodied qualities expressed in phrases he knew well—he was "courteous in manner, easy of address, steady and firm in principle." His place in Wigan, both socially and professionally, will be very hard to fill, but he suffered much and has earned his rest. *Ave atque vale.*

J. O.

On Feb. 27 VIVIAN E. RIDWOOD, B.A., M.R.C.S., L.R.C.P., died at his home in Woodford. He had practised in Bethnal Green for 35 years, except for a period during the last war, when he served over-seas as captain in the R.A.M.C. He had been M.O. to the Post Office and was an examiner for Air Force Cadets and M.O. to the Pioneer Corps, and from 1938 to his death was the London University representative on the Hackney and Spitalfields Exhibition Foundation. But it was as a physician in the districts of Bethnal Green, Spitalfields, and Shoreditch that Dr. Ridwood was best known. He had a large practice in this poor and crowded industrial district, and was much loved for his cheerful presence and his unfailing courtesy and attention to all his patients. He died after a few months of great pain, borne with wonderful cheerfulness and exemplary patience. A memorial service at St. Philip's, Bethnal Green, was very fully attended by his late patients. He will be missed by his fellow practitioners, to whom he was always a good friend.—H. C. D.

The Ashton-under-Lyne district has sustained a severe loss by the death on March 6, after a short illness, of Dr. W. H. HUGHES. He was 79 years of age, was at work to within three weeks of his death, and was the oldest medical practitioner in the area. William Hugh Hughes graduated M.B., C.M., and B.Sc. at Edinburgh in 1889 and also studied at Guy's Hospital and Vienna. In addition to private practice in the town for over fifty years he had served as examining factory surgeon, surgeon to the Borough Police, and honorary and consulting surgeon to the District Infirmary for a commensurate period. He joined the British Medical Association in 1902 and represented his Division at the A.R.M. held in London in 1917.

News has been received of the death on Feb. 19 at Fort Rosebery, Northern Rhodesia, of Dr. S. JEAN MEIKLEJOHN, founder of the Chilubi Hospital and of the Leper Settlement at St. Margaret's. She graduated M.B., Ch.B. at Aberdeen in 1906, was Carnegie Research Fellow in 1912-13 and John Lucas Walker Student 1913-15, and for a time was medical officer to the Dunfermline College of Hygiene and Physical Education. Dr. Joan Lamplugh sends the following appreciation: At an age when most people are content to retire and occupy their leisure with hobbies, Dr. Jean Meiklejohn launched into the strenuous and difficult task of being the pioneer doctor in the White Fathers' Mission at Bangwulu in Northern Rhodesia. She went to Chilubi Island, which lies on Lake Bangwulu on the edge of the swamps where Livingstone died, and in 1937 founded the Hospital of St. Joan of Arc at Santa Maria Mission. The nearest hospitals were each three days' journey by canoe, bicycle, and mail lorry, and for sick Africans without such facilities the journey would have taken very much longer, so the hospital met an urgent need. Working among a primitive and difficult people, with lack of money and materials and skilled help, she nevertheless built up a hospital second to none of its kind. A severe thecal whitlow which she had to open herself without anaesthesia disabled her from operating, and was the occasion for another doctor to join her. From then onwards she concentrated on the leper work and undertook a survey of leprosy in the Bangwulu lake region. The expansion of the work at Chilubi made it necessary to move the lepers from that overcrowded island, and in 1942 she founded a leper colony on the north shores of the lake at St. Margaret's, Kasaba. She was undaunted by the arduous conditions of bush life, and cheerfully undertook supervision of the building of the new colony from the time when the first vegetables in the garden were not yet ready and the timber for the houses not yet cut. She lived for some time in a native hut, and there, as elsewhere, maintained that atmosphere of exquisite taste and civilized living which she carried round with her even when she was living under canvas. She was a painstaking, methodical, and exact clinician and tireless in the treatment of cases under her care. Although when speaking of the surgical needs of Chilubi she complained that she was

"too old a dog to learn new tricks," yet she did in fact become very skilled in leprosy work. She took a long view of the work and was keen on everything that could benefit her lepers, down to the smallest detail of building and gardening. She left the impression of her gracious personality on everything she touched; her loss is all but irreparable and will be most deeply felt by her lepers, to whom she was unfailingly kind. War conditions make the search for a successor an almost hopeless task. She died of blackwater fever.

Dr. A. Griffiths Farr writes from Tanganyika Territory: I have only just received news of the death of FRANCIS WILFRID WILLWAY in a personal letter from home. His obituary notices will, I am sure, have paid due attention to his work in the written art of surgery no less than to his work on the practical side, which was latterly concerned mainly with neurosurgery. They will also have drawn attention to his great organizing ability, to which the citizens of Bristol owe a great deal. It was my privilege to be in contact with F. W. W. for four years as a student and houseman. I shall never forget his teaching, whether by the bedside or in the lecture room; it was clear, logical, concise, and so amazingly complete and delivered so well that it was impossible to forget the main points made. His treatment of patients and of the patient's feelings was admirable and was an object lesson to all. Indeed the closing years of his life were a remarkable example of strength of will and tenacity of endurance. Often in severe pain he continued to work at a phenomenal pace, nor did he neglect, as he might so easily have done, the tuition of students. In his early death medicine has lost an able son and the world a fine citizen.

A correspondent writes: The death of Mr. ARTHUR DONALD GRIFFITH (tributes to whose work and character appeared in the *Journal* of March 18) will be regretted by a wide circle of London colleagues and patients. For a long period he served on the council of the Medical Defence Union, of which he was at the time of his death one of the senior members; on all matters connected with his specialty, as well as on other topics, his opinion was always greatly valued by his colleagues. Stricken recently by an inoperable form of malignant disease, he was able to talk of the inevitable result with a kind of wry humour; this did not conceal the fortitude with which he faced his misfortune. A high-minded as well as an efficient surgeon, his death leaves London the poorer by the loss of one who held a well-deserved place in the affection as well as the esteem of his fellow workers.

*Correction.*—We regret that through a mistake in the card index the last sentence of the obituary notice of Sir Norman Gray Hill (March 25, p. 438) was erroneous. He was unmarried, and therefore left no widow.

## Medico-Legal

### RESPONSIBILITY AND CULPABILITY

At a joint meeting of the Medico-Legal Society with the Section of Psychiatry of the Royal Society of Medicine a paper was read by Dr. W. NORWOOD EAST on responsibility and culpability.

Dr. East said that the psychiatrist was concerned in court with the defendant's fitness to plead, and with the question whether, if he was fit to plead, he had suffered when the crime was committed from a defect of reason due to disease of the mind which prevented him from knowing the nature and quality of his act or from knowing that it was wrong (the M'Naghten rules). The establishment of sanity or insanity on arraignment offered relatively little difficulty, and medical criticism was reserved for the criteria of irresponsibility laid down in M'Naghten's case. The law, however, was elastic, and Dr. East had no doubt that the present procedure and practice resulted in justice to the public as well as to the offender. If a medical formula of criminal responsibility were introduced, the law might insist on a rigid adherence to its specifications, with resulting hardships to offenders and embarrassment to psychiatrists. The urgent need to-day was rather for an improvement in the quality of the evidence given by forensic psychiatrists. Such evidence sometimes stultified itself because the witness allowed an emotional distaste for the legal restrictions concerning responsibility to overcome his scientific judgment. This could not help justice, defendants, or psychiatrists. Medical witnesses would contribute more to the common good by leaving tests of responsibility to the lawyers, and themselves considering more closely the various mental conditions which might properly be regarded from the medical point of view as lessening culpability. No amendment of the law must weaken the defence of the community; nor could the scientific study of criminals always produce exact results.

A convenient classification separated offenders into six main groups: normal, subnormal, mentally defective, psychopathic, psychoneurotic, and psychotic. The conclusion that normality was indefinable was not so sterile as it might appear and might avert mistake in diagnosis. Everyone had his own base-lines of thought, mood, and behaviour, which fluctuated within personal limits. If the fluctuations were dissimilar and excessive, there might be reason to doubt the person's normality. On the other hand, though less violent fluctuations might be evidence of normality, the unfluctuating person was probably fully responsible and therefore punishable. Dull and backward persons formed a large and important class of criminals. They could usually be recognized without difficulty if all the facts were known. There was no reason to consider them irresponsible, but their culpability might well be lessened, as it was in many cases even of high-grade defectiveness.

#### The Psychopath: A Therapeutic Dilemma

The criminal psychopathic personality might be tentatively defined, Dr. East said, as one who was persistently unable to adapt himself to social requirements on account of quantitative peculiarities of impulse, temperament, and character. Medical evidence and ideas might be more precise and practical if the non-progressive cycloid and schizoid personalities were included in this class, which also contained offenders who showed permanent psychic inferiority, temperamental instability, and psychological maladjustment; also the alcoholics, drug addicts, true sexual perverts, and paranoid personalities. Certain criminal conduct might be profitably classified as perversions—analogueous to sexual—of the acquisitive, aggressive, and gregarious instincts. The constitutional inability of the psychopath to harmonize with other persons and situations exaggerated a criminal potentiality. The nearer the condition seemed to lie to mental disease and the further from an anomaly of character, the more inclined would the psychiatrist be to consider whether culpability should be modified. The dilemma of treatment arose particularly in this group. The law might impose a short and ineffective sentence; medically, prolonged detention and treatment might be essential if any possibility of social adaptation were to be exploited. An insufficiently educated public might, however, refuse to tolerate prolonged detention for an offence for which another person might be given a light punishment.

The association of crime with hysteria and anxiety states had probably been underrated and its association with obsessional states overstated. Neurasthenia was occasionally a direct cause of criminal behaviour. Crime was often associated with an early form of psychosis in which the indications of mental disease were so tenuous that the accused had to be adjudged culpable as well as responsible. The psychiatrist might be powerless to prevent a serious crime because the potential offender refused to accept medical treatment and the necessity for his care and control could not be demonstrated with certainty to others. Dr. East deeply regretted the lack of a legal method of dealing with the early psychotic potential law-breaker. This lack, like the neglect to restrict the antisocial and antifamily activities of the alcoholic, was, he thought, a crime of society against itself as well as against the potential offender.

The individual treatment of offenders began with the opening of Pentonville Prison in 1842 and had been continued with the establishment of Borstal institutions in 1908. Some of the proposals in the Criminal Justice Bill, 1938—to establish remand centres and State remand homes for the special medical observation of the young offenders; to permit probation orders to include a provision that offenders who, though not certifiable as insane or mentally defective, were suffering from some form of mental illness or abnormality which was susceptible to treatment might be required to submit themselves to mental treatment; and to introduce sentences of corrective training and preventive detention for special types of offenders—were particularly interesting to psychiatrists. With collaborators, Dr. East had elsewhere recommended the establishment of a special kind of penal institution where research could be carried out into the problems of criminal behaviour and abnormal offenders could be scientifically treated. In conclusion, he said he was confident that the numbers of those whose culpability was modified could be ascertained by investigation, the difficulties of their diagnosis overcome by research, and advances made in the individualization of treatment. For practical purposes the assessment of culpability largely depended upon accuracy of distinction between the inherent constitution of the offender and the results of the impact of disease. The more satisfied the psychiatrist was that a crime was due to faults of character and not to the effects of disease, the more reason would he have to consider the lawbreaker responsible, though he might believe that his culpability was modified.

#### Responsibility and Restraint

The CHAIRMAN (Mr. Roland Burrows, K.C.) observed that a society could survive only if it lived according to rule. The rules of criminal law were difficult to establish and hard to alter and therefore tended to lag behind contemporary opinion. Thus the offender sometimes received much sympathy from persons who were not minded to break the law. Moreover, criminal justice was largely

administered by elderly persons whose ideas were based upon experience of a generation or two ago and who were, *per se*, impervious to later ideas. With the numerical increase of society the importance of the individual offender had grown. An offender was to be treated as irresponsible, the necessary corollary was that he was to be put under some form of restraint—which in itself punishment. For this kind of restraint society must turn to the medical profession. There was much to be said for the proposal to restrict the function of the court to finding guilty or not guilty and to give a separate authority the decision on what should be done with an offender, who should, if possible, be turned into a law-abiding member of society or secluded from it. The duty of sentencing offenders was the most anxious and difficult duty upon the criminal judge.

Brigadier J. R. REES said that the Army had arrived at a fair satisfactory formula for assessing responsibility. No man could be tried by a court-martial if he was found to be insane at the discretion of the convening officer of a court martial if any indication that to do so was wise or necessary. Only about 5% of all offenders in the Army were seen by psychiatrists. Trial was dispensed with only for men who were so defective or psychotic that they had clearly been not responsible at the time they committed the offence and that proceedings could not be held. The Army psychiatrist was in the satisfactory position, by the use of a concise form, of giving expert help to the court as its impartial adviser.

#### The Unconscious Motive in Culpability

Dr. H. CRICHTON-MILLER complained that Dr. East had not gone deep enough but had left the impression that the present system could be adapted to the needs of real justice. The whole concept of motivation had been transformed in the last few years, and the psychiatrist now had to deal with problems of culpability in the presence of unconscious motives which were perfectly clear to him but absolutely hidden from the public and the judiciary. He gave as an example a well-to-do woman shop-lifter who was incurably deaf, was developing a paranoid system, and had been thwarted in her desire for a son by the refusal of her husband to have any more children. She could have been helped, but the magistrate took the view that she ought to know better, and gave her a fairly severe sentence, which could not possibly have benefited her. The idea of temporary irresponsibility must imply the possibility of conduct that could not be treated in the ordinary way. Both psychiatrists and lawyers should clarify the difference between the deterrent and the educational elements in a sentence. He would have agreed with the magistrate who had said, when sentencing the shop-lifter, that he was obliged to do so for purposes of deterrence. Doctors must accept deterrent punishment for their patients, but wholly useless forms of punishment were to be deprecated. Mr. G. R. BLANE WHITE, K.C., pointed out that the Army had no procedure appropriate for many mental cases, and only deterrent sentences could be given. Dr. W. H. SHEPLEY declared that the legal point of view over-valued consciousness and did not give due regard to the unconscious. Delinquents could not be improved except by a person whom they felt to be on their side and to understand them. Only such a person could begin to understand their motives, of which they themselves were largely unaware.

Lieut.-Col. J. E. W. PEARCE said that any major change in law or judicial procedure should be based upon systematic psychiatric studies of antisocial conduct, such as those provided for by the Criminal Justice Bill. To do something to reform an offender must be more useful for society than to put him away for the time being. It might well be contrary to the welfare of society that a persistent sexual offender should be at large, particularly during the early stages of his treatment. The psychiatrist's help began after guilt or innocence had been determined; he should be called upon for expert evidence to assist the court in passing sentence. Psychiatrists recognized that a sharp punishment at the very outset of the delinquent's career was very often efficacious. Punishment based merely upon expiation and retribution had been proved ill advised. For the protection of society punishment must be both deterrent and reformative. A small advisory committee should be set up to prevent waste of time in overlapping research into delinquency. Some of the arbitrary age limits—e.g., the presumption that a boy below 14 could not have carnal knowledge—should be swept away. Dr. ROWLAND HILL stressed the difficulty of distinguishing between a psychopath and a healthy person who had been brought up in an abnormal environment. Many habitual criminals had an abnormal childhood. The domiciliary service of supervision and control of antisocial people should be enormously extended, and the care committee might well have a large number of voluntary workers associated with it to relieve the pressure on the overworked probation officer.

Dr. NORWOOD EAST, in reply, warned against too rapid an introduction of deep explanations of crime, which might much offend the public and hamper the development of suitable methods. Doctors should study minor mental abnormalities more closely. The provisions of the Criminal Justice Bill would give a great impetus to the medical profession to help in the treatment and deterrence of crime.

## Universities and Colleges

### UNIVERSITY OF EDINBURGH

brigadier F. A. E. Crew, M.D., D.Sc., F.R.S., has been appointed to succeed Prof. P. S. Lelean in the Bruce and John Usher chair of public health. He has held the Buchanan chair of animal genetics in Edinburgh since 1928 and was temporarily released from the duties of his professorship some two years ago for work in the Medical Department of the War Office.

### UNIVERSITY OF GLASGOW

A series of meetings will be held in the Department of Ophthalmology on Wednesdays, from April 5 to May 10, at 8 p.m. The meetings are open to all medical practitioners and senior students interested in ophthalmology.

### UNIVERSITY OF LEEDS

At a meeting of the Council of the University of Leeds on March 14, part-time Lectureship in Public Health was instituted, and Dr. F. R. Dennison, honorary demonstrator in that subject, was appointed to be the new post.

### UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

**FINAL M.B., Ch.B.—Part I:** Audrey M. Ashcroft, N. L. Bailes, K. Baker, J. Beacon, D. T. Burns, P. Brealey, P. M. Breidahl, Helen A. Carson, V. D. Charnley, M. H. Clark, J. N. Coulshed, S. Croft, G. D. Currie, Pauline M. Dean, Joan Evans, R. L. Goldson, H. G. Graham, J. E. A. Harris, Ailsa M. Heath, Nellie Hughes, J. F. G. Ince, R. W. Kennon, Barbara M. Kulick, C. S. Law, Jean Leary, D. C. Levinson, H. S. Levy, T. R. Littler, H. A. P. Garra, A. E. Pritchard, Rachael M. Rawcliffe, G. P. Reed, H. Roberts, W. C. Roberts, P. W. Robertson, F. W. Sheffield, H. H. Slack, Helen M. Taylor, L. Temkin, R. G. Thomas, Maureen M. Tickle, H. F. Tinker, Ward, Joyce Watson, J. N. P. Watson, W. F. Wille, E. H. Wilson, E. Wren, Aline N. Wynne, *Passed in Separate Subject:* Cécile N. Broster (Pharmacy and General Therapeutics). **Part II:** M. K. Alexander, J. T. D. Allen, E. T. Anderson, Beril G. Anson, G. Ansell, K. W. Baruch, J. P. D. Bates, J. J. Boag, Edna M. Brown, D. Craddock, H. T. Davenport, B. Dover, Monica Driskill, E. D. Edmondson, J. L. Edmondson, J. W. Edwards, R. E. Ham, P. Foster, J. J. C. Frew, B. R. Frisby, J. D. A. Gregson, R. Griffiths, B. B. Harrison, C. R. Helsby, G. Hughes, L. Jacobs, D. C. R. Jones, E. S. Jones, H. A. Jones, R. S. Jones, M. Kirwan, J. W. T. W. Lawson, J. Joyce, R. Lewis, J. B. Lynch, J. B. McCarthy, M. G. McEntegart, C. H. Martlew, Lucille F. Morgan, D. B. Mossman, C. M. O'Neill, C. A. Newson, H. H. Philne, Muriel E. St. Pier, W. L. Sanders, J. J. Shepherd, Isabel S. Smellie, J. G. W. Storey, P. J. Taylor, W. A. Thompson, Corris E. Venables, H. Wickham, J. R. E. Wilson, *Passed in Separate Subject:* Lipton (Public Health).

<sup>1</sup> Distinction in pharmacology and general therapeutics. <sup>2</sup> Distinction in forensic medicine and toxicology. <sup>3</sup> Distinction in public health.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND

The President, Sir Alfred Webb-Johnson, gave a luncheon on March 10 at the College in honour of Major-General Norman T. Kirk, Surgeon-General of the United States Army. Those present were: The United States Ambassador; Dr. E. A. Strecher, Consultant to the Secretary of War; Major-Gen. David N. W. Grant, Air Surgeon, U.S. Army Air Force; Major-Gen. Paul R. Hawley, Chief Surgeon, E.T.O., U.S. Army; Brig.-Gen. Malcolm C. Grow, Surgeon, J.S. Strategic Air Force; Col. Elliott C. Cutler, Chief Consultant in Surgery, E.T.O., U.S. Army; Col. James C. Kimbrough, Chief of Professional Service, E.T.O., U.S. Army; Col. Rex L. Diveley, Senior Consultant in Orthopaedic Surgery, E.T.O., U.S. Army; Col. Derrick T. Vail, Senior Consultant in Ophthalmology, E.T.O., U.S. Army; Col. Herbert Wright, Chief of Professional Services, J.S. Strategic Air Force; Surg. Vice-Adml. Sir Sheldon Dudley, Medical Director-General, Royal Navy; Lieut.-Gen. Sir Alexander Hood, Director-General, A.M.S.; Air Marshal Sir Harold Whittingham, Director-General, R.A.F.M.S.; Major-Gen. R. M. Luton, Director, Medical Service, Canadian Forces in England; and seven other members of the Council of the College.

A series of Hunterian Lectures commencing on Wednesday, April 12, and a Thomas Vicary Lecture on Thursday, April 13, will be given at the College (Lincoln's Inn Fields, W.C.). All the lectures begin at 4 p.m. and are open to advanced students and medical practitioners.

### COLLEGE OF PHYSICIANS AND SURGEONS OF BOMBAY

The Council of the College of Physicians and Surgeons of Bombay at its meeting in July, 1943, decided to institute an examination for a diploma in child health (D.C.H.Bom.) and appointed a committee to draw up regulations for that examination. The committee submitted its report to the Council on Jan. 14, 1944, and the report was approved and adopted. The course, which is of twelve months' duration, has to be taken at a recognized children's hospital or in a recognized children's department of a general hospital. The examination is open to persons holding a qualification (a) laid down in Schedules I and II of the Indian Medical Council Act, 1933, or (b) granted by any of the various Examining Boards in India whose names were on the Schedule of the Bombay Medical Council in 1941.

## The Services

Capt. E. T. McCartney, R.A.M.C., has been awarded the M.C., and Major (temp. Lieut.-Col.) P. J. May, M.B.E., Capt. (temp. Major) C. B. Marsden, and Lieut. A. P. Binks, R.A.M.C., have been mentioned in dispatches in recognition of gallant and distinguished services in the field.

Capt. J. A. L. Naughton, R.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in Italy.

Surg. Lieut.-Cmdr. E. S. McPhail, R.N.Z.N.V.R., has been mentioned in dispatches for outstanding courage, enterprise, and devotion to duty in H.M.N.Z.S. *Leander* in an action with Japanese Forces.

The following appointments, awards, and mentions in recognition of gallant and distinguished services in Sicily have been announced in the *London Gazette*:

**C.B.E. (Military Division).**—Col. (temp.) A. A. Eagger, O.B.E., R.A.M.C.

**O.B.E. (Military Division).**—Col. (temp.) C. Donald; Majors (temp. Lieut.-Cols.) P. Lloyd-Williams, T.D., F. O'Driscoll, W. A. Robinson, H. L. W. Sixsmith, M.B.E., W. L. Spencer-Cox, M.C., R.A.M.C.; Capt. (temp. Major) E. A. Jack, R.A.M.C.

**M.B.E. (Military Division).**—Capts. (temp. Majors) R. Bolton, L. F. W. Salmon, R.A.M.C.; Capt. H. K. Lucas, R.A.M.C.

**M.C.**—Capts. A. Noble and D. G. Sheffield, R.A.M.C.

**Mentioned in Dispatches.**—Brigs. (temp.) S. Arnott, D.S.O., R. R. G. Atkins, O.B.E., M.C., R. W. Galloway, C.B.E., D.S.O., E. Phillips, C.B.E., D.S.O., M.C., late R.A.M.C.; Cols. (temp.) W. M. Cameron, O.B.E., A. T. B. Dickson, O.B.E.; Major (temp. Lieut.-Col.) (Acting Col.) J. C. Gilroy; Majors (temp. Lieut.-Cols.) A. McC. Campbell, R. McL. Gordon, D.S.O., D.F.C., G.M., F. H. Hollingshead, R. G. M. Keeling, O.B.E., C. H. Kerr, D.S.O., M.C. Paterson, M.C.; Capts. (temp. Majors) J. W. L. Bain, L. Brill, G. C. Dancy-Browning, W. S. Harvey, F. C. Heatley, C. J. Longland, A. J. R. Lowdon, M. M. Medine, M.B.E., C. J. B. Murray, A. D. Wall; Capt. (Acting Major) R. W. Jones; Capts. A. Green, D. C. Little, J. B. MacKay, B. C. M. Palmer, R. Paul, D. R. Sandison, A. L. Thorp (died of wounds), R.A.M.C.; Major (temp. Lieut.-Col.) J. Morgan, O.B.E., I.M.S.

### CASUALTIES IN THE MEDICAL SERVICES

Acting Wing Cmdr. DONALD SCRINGOUR BATEMAN was killed in a flying accident over-seas on March 14, aged 40. He studied medicine at Oxford University and St. Thomas's Hospital, qualified in 1930, and took the M.B., B.Ch. degrees in 1936. He obtained the Diploma in Child Health in 1935 and the M.R.C.P. in 1937. He was appointed to the Medical Branch, R.A.F.V.R., on April 18, 1939, and was called up for service at the outbreak of war. At the time of his death he was physician in charge of the medical division of an R.A.F. hospital over-seas.

Acting Squad. Ldr. HUGH FERGUSON DAVIDSON WHITELAW died on March 15 at the age of 34. He studied medicine in Glasgow and took the Scottish Triple Qualification in 1934. He entered general practice in 1935 and was appointed to a commission in the Medical Branch, R.A.F.V.R., on Jan. 7, 1941. At the time of his death he was medical officer at an R.A.F. Wing Headquarters at home.

Acting Squad. Ldr. EDWARD TUDOR OWEN died on March 17 while on active service over-seas, aged 34. He studied medicine at Liverpool, graduated M.B., Ch.B. of the university in 1933, and obtained the F.R.C.S. in 1941. He held surgical appointments at various hospitals in the Liverpool and Manchester areas and received a commission in the Medical Branch, R.A.F.V.R., on Oct. 8, 1942. At the time of his death he was serving with a mobile field hospital over-seas.

**Wounded.**—War Subs. Capt. B. P. Armstrong and C. M. Boucher, and Lieut.-Col. J. N. Groves, R.A.M.C.; Wing Cmdr. T. D. L. Bolan and Acting Wing Cmdr. C. R. Jenkins, R.A.F.

**Killed.**—War Subs. Capt. J. J. Docherty, R.A.M.C.

**Killed on active service in Burma.**—Capt. H. Lauder, R.A.M.C. Previously reported missing, now presumed lost at sea.—Lieut. N. Jolly, R.A.M.C.

**Died.**—War Subs. Capt. J. S. G. A. Burns and J. Sheehan, R.A.M.C., Capt. H. Mullen, R.A.M.C.

**Prisoner of war.**—Lieut. R. L. G. Dawson, R.A.M.C.

### DEATHS IN THE SERVICES

Col. GEORGE HUTCHESON, I.M.S. (ret.), died on March 14 at Douglas, Isle of Man. His father, George Hutcheson, had entered the Indian Medical Service in 1873 and had written on cholera. George Hutcheson, jun., was born in India on Dec. 17, 1874, and educated at the Brighton and Epsom College and the London Hos-

pital. He passed both the Conjoint Board and the London University final medical examinations in 1897 and 1898 and entered the I.M.S. in the latter year. He saw active service in China in 1900 and received the medal. On entering the civil branch he joined the jail department and held charge of various large central jails; the work of these includes administrative as well as medical charge. He was promoted to the rank of major in 1910 and of lieutenant-col. in 1918. In 1927 he was selected for the administrative grade and was appointed to be Inspector-General of Civil Hospitals and of Prisons, Assam; he retired on completion of his term in that post. He joined the British Medical Association in 1908.

## Medical Notes in Parliament

### National Health Service Debate in the Lords

When the debate on the White Paper was resumed in the House of Lords on March 21, Lord HORDER said he believed that the Government's intentions were honourable, but good intentions were not enough when the question at issue was such an expert one as that of not only maintaining but increasing the national health services. Careful analysis of the White Paper did not convince him that the knowledge and experience that we actually possessed in these matters had been fully utilized in framing the Government's scheme. If the White Paper was only a tentative expression of the Government's ideas of how a national health service might be run and was open to modification after further discussion with those who actually ran these services to-day, his own fears were to a large extent allayed; but if the White Paper as it stood was to be made the basis of an Act of Parliament, discussion being subsequent and not prior to the drafting, certain principles and institutions of paramount importance to the efficiency of our health services were likely to be lost to us. The White Paper posed an administrative structure which threatened the very existence of two of the institutions in British medicine which both past and present experience showed to be vital—the private practitioner and the voluntary hospitals. It was true that it said that both of these institutions were to be allowed to remain, but their continued recognition was not definitely encouraged. It was permissive, and they must fight for their survival.

The attitude of the White Paper towards the man who wanted to continue private practice and yet avail himself of the manifest advantages to his patient that this new scheme offered was too colourless, if not actually negative. Almost it read as though some patients preferred to be doctored privately, and so, as this was still a free country, their whim was to be indulged, for a while, anyway. It was very much the same in regard to the voluntary hospitals. It was certainly not the wish of the Government, the White Paper said, to destroy or diminish a system so well rooted in the good will of its supporters. But this expression of a mere desire for co-operation, this permission to continue to exist, demonstrated a great lack of appreciation of the intrinsic value for the nation of an institution in which there had resided for hundreds of years, and still resided, the best that British medicine held in respect of both its science and its art. The White Paper dismissed medical research in a few lines. It said that it had been the policy of the Medical Research Council to encourage research work in the hospitals and to assist it financially. He agreed that that was a good policy, as against the alternative one of setting up super-State institutions for this purpose.

The voluntary hospitals should have not only permission to exist but positive encouragement and a guarantee of financial security. He shared the anxiety of those who, while recognizing that the Government scheme did not kill the voluntary hospitals, feared that it might quickly starve them into inanition. The Minister of Health said he could not believe that the anxiety shown was really justified. If so, then it was a duty laid upon the Minister to allay this anxiety, because the expression of it had been very real and very general throughout the country. He did not think anyone could say what might be the ultimate type of hospital service in this country, how controlled, how administered, how financed. But most doctors believed it essential to maintain the voluntary hospitals pending the proposed development in the hospital service, whether the view was short or long. Most of them believed that it was not in the best interests of the health of the nation that the medical profession should be a branch of the Civil Service. But what the public believed was more important than what doctors believed. The Government should take some steps to enlighten the public on the real implications of the White Paper before an Act of Parliament was framed in relation to it. If this were done, public opinion would take much the same view as the doctors. Some of them felt, not that there was too much of the spirit

of democracy in the White Paper, but that there was not enough democracy in it. The White Paper smelt too much of bureaucracy.

### The Central Authorities

The principle of professional and vocational guidance appeared to be traversed, in the suggested administrative machinery, at the centre and at the periphery. The Central Health Services Council was not appointed by the profession or by professional organizations. It had no executive power and, presumably, might not publish its reports. The Central Medical Board had executive power, but here again nomination was by the Minister and not by professional organization. In the case of hospitals the anomaly called for special consideration. He was very doubtful if in this case anything short of *ad hoc* hospitals board would resolve the conflict that would undoubtedly face the Minister. Such a board should certainly be set up. Care should be taken to see that the areas chosen for the hospitals and allied services should be large enough to embrace all types of hospital and clinic in close liaison, working always upwards to a key hospital, which should be, whenever possible, a teaching hospital of university status.

He confessed to some surprise when he read the Minister of Health's comment on the cottage hospitals—namely, that the old conception of the local hospital was outworn. He awaited with interest the comments of the admirable boards who ran these splendid institutions. He was convinced that, given proper vocational representation on the controlling and administrative bodies, both central and local, the development of Health Centres would bring about that availability of our health services which was the essence of the problem. In those Health Centres the Government could nourish that spirit of adventure and enterprise which lay at the heart of British medicine, and which the shadow of some parts of the White Paper threatened to obscure. Ministers and the accredited representatives of medicine, by coming together, could make satisfactory adjustments in this suggested scheme. He wished that medicine could offer the Government what he and some of his friends dreamt of but had not so far realized—an Academy of Medicine in this country for these deliberations, a body which would be authoritative, representative, and judicial. But, failing that, there were bodies with which the Government had already made contact, bodies animated by good will and by a desire to do the best in this matter for the people of this country.

Lord GEDDES said it was true that social security did make being ill a gainful occupation, and it was probable that a certain number of people might like to continue in that easy occupation of making an income on the flat of their backs in bed. Therefore there had to be certification by medical people. There was no elaboration in the White Paper of how the consultant service was to be trained and developed, and not very much about how it was to be administered; but one thing was clear, and that was that it was to be administered by, and under the control of, the hospitals and the local authorities concerned. That was an extraordinary position. The general practitioners would be under the control of the Central Medical Board, which was, as he read it, a mainly bureaucratic body controlled by the civil servants of the Ministry of Health acting in the name of the Minister. They were to lay down the conditions of certification as to whether those who thought themselves sick were to be allowed to continue in the gainful occupation of being sick. The general practitioners would have a contract in which were stated the conditions on which they were to certify.

### A Medical Gestapo

There must be certification for any security plan and a medical inspectorate, and if that did not degenerate before very long into something not very dissimilar from a "medical Gestapo" he did not know the way the Civil Service of this country worked. What would happen was that they would have this continual supervision of every person who, on medical grounds, was a beneficiary under this plan. There was no way of escaping that. If they were going to have a security plan with medical benefit on a great scale there must be certification. If it was to be safe, there must be some way for the wage-earners who were caught by the certification to get to independent medical opinion. Therefore he was profoundly disquieted by the suggestion in the White Paper that everybody was to be insured. In the interests of them all there should be an uninsured class of people in the country—obviously in the upper income limit—and they would, of course, pay for the real health service, not this health service through taxes and rates. If they were not insured they would be adequate to maintain a strong body of independent leaders of the medical profession, to whom appeal could be made from decisions of the doctors controlled by the Central Medical Board. That there should be such an independent group of doctors was of the greatest possible importance. The Government should look at that point again; because this

# OESTROFORM

Trade Mark

*Standardised natural oestrogenic hormone*

Whenever indications for oestrogenic hormone therapy are present, Oestroform will be found to act in a specific manner. Being the natural oestrogen, it is readily tolerated in all cases, and its use is free from the untoward toxic effects that sometimes occur when the synthetic substances are administered.

Oestroform is indicated in the treatment of —

- Climacteric and menopausal disturbances
- Oligomenorrhœa and amenorrhœa
- Delayed puberty in the female
- Sterility and dysmenorrhœa due to uterine hypoplasia
- Pruritus vulvæ and senile vaginitis

Oestroform is indicated also in certain conditions associated with pregnancy, as, for example, missed abortion, the induction of labour, uterine inertia and the inhibition of lactation.

*Details of dosage and other relevant information will be gladly supplied on request.*

## THIOUREA & THIOURACIL

*in the treatment of*

### THYROTOXICOSIS

Recent reports\* indicate that the oral administration of thiourea or thiouracil is likely to prove an important therapeutic measure for controlling hyperthyroidism.

The effect of either substance in its appropriate dosage is a general abatement of symptoms, consisting of reduction of pulse to normal, increase in weight, and fall of basal metabolic rate, etc.

\* Lancet 1943, 2, 465. B.M.J. 1943, 2, 783.

Thiourea and thiouracil are now available in tablet form, convenient for oral use.

#### THIOUREA

In tablets each  
containing 5 grains.  
Packs of 100 and 1,000.

#### THIOURACIL

In tablets each  
containing 1½ grains.  
Packs of 100 and 1,000.

*Literature available on request.*

GENATOSAN LTD., LOUGHBOROUGH, LEICESTERSHIRE

# 'TABLOID' BRAND 'Methedrine'

*d*-N-methylamphetamine hydrochloride

'METHEDRINE' brand *d*-N-methylamphetamine is a sympathomimetic substance allied to ephedrine but possessing a pronounced stimulant action on the central nervous system and particularly on the cerebral cortex.

In therapeutic oral doses it increases the speed of cerebral action and promotes euphoria without significant elevation of blood-pressure.

INDICATIONS Schizophrenic stupor; narcolepsy; anxiety neurosis; post-encephalitic Parkinsonism; overdosage with hypnotics or sedatives; alcoholism and morphinism; epilepsy (in cases under barbiturate therapy); depression and asthenia.

'TABLOID' BRAND 'METHEDRINE,' 5 mgm.

BOTTLES OF 25 .. 1/8 (PLUS 2½d. PURCHASE TAX) • BOTTLES OF 100 .. 5/6 (PLUS 8½d. PURCHASE TAX)

Subject to Medical discount

Also available for parenteral administration 'HYPOLOID' BRAND 'METHEDRINE,' 30 mgm. in 1.5 c.c.

**PHILIPS  
MOBILE 'D'  
DIAGNOSTIC  
X-RAY UNITS**

This fine 90/30 Mobile X-Ray Unit, ideal for ward use and for emergency purposes, is widely recognised as the foremost equipment of its class. Modern in design and conception and manufactured in large series, it incorporates numerous outstanding technical advantages which are described in full in publication XMI, available on request. In radiographic performance the MOBILE 'D' is superb and, above all, it is thoroughly reliable. Authorised purchasers will find this equipment a highly satisfactory investment. Enquiries are invited.

QUICK DELIVERY • BRITISH MADE THROUGHOUT

document was based upon the idea of treatment of ill-health. It must necessarily increase the vested interest in ill-health, because it was raising the amount of money spent on dealing with it.

Medicine was a continually growing science and art, changing year by year under the influence of the great teaching hospitals. They must do their best to keep in the van of medical knowledge, medical research, and medical teaching. That meant that the great teaching hospitals—which would be, which must be, any complete scheme of hospital organization the key hospitals of great regions—must be governed by bodies of men who understood fully what medical research, medical science, and medical teaching meant.

Lord BALFOUR OF BURLEIGH said he was assured that more than 1,000,000 people in this country, drawn from all classes of society, relied upon homoeopathic treatment. He did not fully grasp how the homoeopaths were satisfactorily to be fitted to this scheme.

### "Power of Direction"

Lord WOOLTON, who replied, said that there was no doubt in the mind of the Government about the value of scientific research in general and medical research in particular. He would have a conversation with the responsible Minister with regard to the homoeopaths. The Government had tried, in the development of this scheme, not to destroy but to build up from what they had a new system that would grow out of the old. The concern of Lord Moran and Lord Horder about the Government's relation to the Central Health Services Council and what the Government was going to do with the profession was unnecessary. The Government was most anxious to co-operate in every sort of way with the medical profession, to consult them, and to do everything with them—except one thing. Ministers were determined that they would take the responsibility for their actions, and they were not going to put that responsibility on to a medical board. There was no insincerity in the White Paper. When the Government said, therefore, that it was going to have a "medical council" it was not something merely put up as a screen; it was a deliberate effort to get the best of medical opinion to advise Ministers. The Government did not say, "Here is the legislation; you can take it or leave it." The profession would be consulted throughout before legislation was brought in.

The White Paper contained no proposal in any way analogous to the power of direction at present exercised by the Government under the National Service Acts. The true position was this: there was an assumption by the community as a whole of the responsibility for guaranteeing to every member of it the services of a family doctor. That was what the Government was guaranteeing, and that involved new duties with regard to the distribution of medical practice. The Government must do what it could, without regimentation of the profession, to see that every area had enough doctors to meet the needs of the patients, which was not always the present position. Two proposals were therefore made in the White Paper for methods to be used by the Central Medical Board for this purpose. The first was that the board should be able to say that a particular area already had enough doctors to carry on the public service, and that no newcomers into the public service should be allowed in that area. How restricted this power was and how little it resembled direction, even of a negative kind, was clear from the fact that it did not apply to private practice. Any doctor would be at liberty to practise privately wherever he liked and at any time he liked. Moreover, it applied only to newcomers to an area and did not in any way disturb or affect the doctors already practising there, and it did not involve directing any doctor to go anywhere. It merely restricted the range of his choice of the area in which he would take up practice in the public service. When a young man wished to enter a public service where he would be paid out of public funds, it was not a very hard condition that he should be told where there was a vacancy and where the State was prepared to pay him to do his work. There had been misunderstanding on this point.

The Government did not want the voluntary hospitals to pass. It had deliberately stated that the sum total of the cost of this National Health Service would not be met by rates and taxes or by contributions under the insurance scheme—that all those put together would not be enough to maintain all the hospital services and all the other services that would be required. Therefore it would be necessary for the voluntary hospitals to continue. There was no reason to be fearful on this question. Both by word and deed the Government would do whatever it could to maintain the existence of the hospitals in full vigour.

The Government was anxious to develop a consultative service for the whole community. Before legislation it would enter into the fullest discussion with reference to the position of consultants and the training of consultants. There was in

this country a great medical and hospital service, but the thing the Government had in mind was a programme of positive health for the people. Through this legislation the country would benefit immeasurably, and he hoped that Lord Moran would come in on to the Government side and not divide the House on this question.

Lord MORAN withdrew his amendment, and the motion welcoming the Government's proposals was agreed to.

### Rehabilitation in the Air Force

In the House of Commons on Feb. 29 Sir ARCHIBALD SINCLAIR made a statement on the Air Estimates. Referring to the accident rate he said that though statistics showed that it was declining they were not satisfied.

Every accident represented a lamentable waste, certainly of labour and materials and perhaps of precious life and skill. Moreover, as our aircraft became larger, more lives were risked every time an accident happened. It was our duty to see that each member of a crew, whose lives might depend on any one of their number, was as skilled, practised, and swift in thought and action as training could make him. Another source of wastage which had been reduced was sickness. Though more of our units were serving over-seas, often in unhealthy areas and under active war conditions, we had had, during the last 12 months, fewer sick than at any time since the outbreak of war. That certainly meant much in avoidance of pain and suffering; but it also meant the addition of several thousand men and women to our resources. The R.A.F. owed a great debt to the medical profession, both to those members of it whose career lay in the R.A.F. Medical Branch and to the many doctors and surgeons who had joined it since the war started.

Remarkable strides had been made in the rehabilitation of men suffering from burns, severe wounds, and accidents. The rehabilitation centres worked on the principle that it was not enough that a broken limb or a torn ligament or burnt fingers should be mended if the patient was nevertheless to limp or lose part of his skill of hand for the rest of his days. Members knew the tragedy of industrial cases and the fear that haunted the patient that he would never get back to full work again, and they would be glad to hear that over 80% of the patients in the centres had been able to get back to full duties in a shorter time than a few years ago we should have believed possible. So, under the wise and vigorous leadership of Air Marshal Sir Harold Whittingham, the Director-General of Medical Services, doctors and dentists contrived not only to heal but to prevent sickness, and thus strengthen the R.A.F. for battle.

### Royal Commission on Population

Mr. CHURCHILL announced on March 2 that Mr. Willink had appointed three committees to assist the Royal Commission on Population respectively on the statistical, the economic, and the biological and medical aspects of the inquiry. The secretary of the Royal Commission itself and of the three committees was Mr. N. F. McNicoll of the Ministry of Health. The terms of reference of the Commission were:

To examine the facts relating to the present population trends in Great Britain; to investigate the causes of these trends and to consider their probable consequences; to consider what measures, if any, should be taken in the national interest to influence the future trend of population; and to make recommendations.

The medical members of the Commission are Prof. A. W. M. Ellis, who is chairman of the Biological and Medical Committee, and Dr. Ethel Cassie.

The terms of reference of the Biological and Medical Committee are: To formulate for the assistance of the Royal Commission on Population the biological and medical factors relevant to the Commission's inquiry and generally to advise the Commission on the biological and medical aspects of the inquiry. The members of this committee in addition to Prof. Ellis are Prof. E. D. Adrian, Prof. D. Baird, Dr. P. M. F. Bishop, Dr. C. P. Blacker, Mr. Eardley Holland, Dame Louise McLroy, Dr. A. S. Parkes, Mr. E. W. Riches, Sir Alexander Russell, Dr. Percy Stocks, and Dr. J. G. Thwaites.

### Army Medical Services

Replying on March 2 to the debate on the Army Estimates. Mr. ARTHUR HENDERSON said the Army Medical Service, including the Army Dental Service and Queen Alexandra's Imperial Military Nursing Service, had been strained owing to shortage of doctors. The Army Medical Service had accepted as an additional responsibility the care of Yugoslav wounded. The doctors available were insufficient to meet the needs of the fighting Services and of the civil population. Medical personnel were in many instances unavoidably overworked. They had accepted this cheerfully and with zeal and efficiency, had

surmounted all difficulties, and produced excellent results. Every effort was made to replace medical officers, where possible, by non-medical officers, R.A.M.C., in appointments which could reasonably be filled by persons who lacked medical qualifications. The Army had cut down its demands for doctors to the minimum, but the minimum was unlikely to be supplied. The Army Council would be able to meet the demands of the Forces engaged in future on active operations, but the Army at home would not receive the same high standard of medical service which it had in the past. Every endeavour would be made to see the sick were well cared for and did not suffer. There were bound to be delays and imperfections in medical boards, specialist examinations, the answering of complaints, and other administrative activities which were not matters of life and death. These must be accepted.

#### Rescue Ships of the Navy

In introducing the Navy Estimates in the House of Commons on March 7, Mr. A. V. ALEXANDER referred to the reduction in the loss of shipping tonnage. He said that this reduction had been reflected in the Merchant Navy casualties, and that in 1943 the number of officers and men lost was roughly only half of that in 1942. The Admiralty, in consultation with the Ministry of War Transport, had been able to increase substantially the number of the special rescue ships which were sailed with convoys now for the sole purpose of rescuing survivors and giving medical attention. Each carried a naval doctor and a hospital staff, and they were now an integral part of the convoy system. There had been many reports from the naval escorts praising the high standard of seamanship and efficiency of the masters, officers, and crews of these vessels, which had been operated with magnificent courage.

#### Antibacterial Cream for Burns

In reply to Mr. Kirkwood on March 14 Mr. JOHNSTON said he was informed that Prof. Todd and his assistants at the Royal Technical College, Glasgow, in collaboration with the Glasgow Royal Infirmary, had produced a formula for a cream for use as a skin disinfectant and as a first-aid treatment for burns. Claims recently made for this preparation in the Press went further than those responsible for the formula would desire, but Prof. Todd and his staff had performed a valuable public service in evolving this exceedingly helpful formula. It was described in the *British Medical Journal* for March 4 in a letter from Dr. Leonard Colebrook, who was sent to Glasgow by the Medical Research Council to undertake investigations.

#### Venereal Diseases

Mr. GRAHAM WHITE on March 16 inquired whether the Minister of Health was satisfied with the progress made in dealing with venereal diseases under Regulation 33B, and if he would take further measures to prevent this evil from spreading. Mr. WILLINK said that in his view Regulation 33B had been of considerable help to local authorities in tracing and securing treatment of persons who did not voluntarily seek and undertake it. The Regulation was not designed to do more than deal with a comparatively small class of infected persons who had always been a special problem. He had under special consideration what further effective measures could be taken to deal with these diseases, but was not yet in a position to make a statement.

In answer to Mr. Sorensen on March 14 Sir JAMES GRIGG said that in the years 1940 to 1943 inclusive there were in this country on the average just under 11 fresh cases a year of venereal disease per 1,000 troops. The average figure for 15 to 1918 inclusive was 29½ per 1,000, but these figures included relapses as well as fresh cases. They were not, therefore, strictly comparable with the present figures, but showed that there had been a substantial decrease. Of men discharged from the Army on medical grounds, 3 per 1,000 were discharged on account of venereal disease. Every method in the way of education, provision of recreation, prophylaxis, and treatment was being actively investigated with a view to decreasing wastage from these essentially preventable diseases.

#### Examination of the Eyes of School-children

Mr. BUTLER said on March 16 that in 1938 the number of ophthalmic surgeons employed by local education authorities in the school medical service was 418. Comparable figures for the war years were not available, but he had no reason to think that the number had fallen materially. School medical officers and assistant school medical officers employed by local education authorities on eye work in 1938 numbered 226. The records did not show how many of them had specialist qualifications. Before the Board approved the employment of a school medical officer on eye work they satisfied themselves that he had adequate qualifications and experience.

#### Functions of Ministry of Health

Asked on March 16 to reduce the field of activity of the Ministry of Health to enable the Department to deal with matters of prior importance, Mr. CHURCHILL said that proposals which the Government would shortly make in regard to social insurance would involve reconsideration of the responsibilities of several Departments, including the Ministry of Health. Apart from this and the possibility of minor adjustments in departmental boundaries, he was satisfied that the functions of the Ministry of Health covered a well-defined and manageable field of action.

#### Diphtheria Immunization

On March 21 Mr. WILLINK, replying to Mr. Alfred Edwards, said that the number of cases in England and Wales in which it had come to his notice that death had taken place shortly after immunization by toxoid against diphtheria was two. It was estimated that about five million children had been given protection by this means in the last few years. The number of reported cases in which "nervous trouble" had been noted some time after immunization was 16. The relationship between the nervous trouble and the process of immunization had not been established. Whenever practicable, inquiries were made by medical officers about such cases.

*Malaria Research Institute.*—On March 1 Major LYONS asked whether the Secretary of State for the Colonies would, as an economy effort, establish a malaria research and survey institute for the Central African Colonies, on the lines of the one in India, to be financed by the Colonial Research Fund, or one each for West and East Africa respectively. Mr. EMRYS-EVANS said that research on malaria was being actively carried out at present so far as circumstances permitted. Much work on malaria control had been done and was being done both in East and in West Africa. The general organization of medical research in the Colonial Empire, which would include the most suitable means for investigating the problems of malaria and its control, was at present under consideration by the Colonial Research Committee.

*Allowances for Tuberculous Persons.*—Answering Mr. Graham White on March 2, Mr. WILLINK said arrangements for the payment of treatment allowances in cases of tuberculosis had been made by all county councils and all county borough councils. Special arrangements for meeting the cost of these allowances from the Exchequer were introduced as a wartime measure on the ground of the importance, from the point of view of the war effort, of dealing with certain cases of this disease. Where this consideration did not apply the question of amending existing provision for maintenance was being considered as part of the arrangements for social insurance.

*Women Medical Students' Accommodation.*—On March 7 Sir E. GRAHAM-LITTLE asked the Minister of Health whether he was aware that the Senate of London University desired to extend facilities in its medical schools for women students, but that one of the principal obstacles thereto was the inadequacy of the accommodation for men and women in the university's medical schools, which now trained nearly half the doctors of this country; and whether he would give particular attention to this position in framing his future estimates. Mr. WILLINK replied that he was aware of the resolution on the subject of the training of women medical students recently passed by the Senate of London University, and he understood that a copy of it was being sent to the Committee on Medical Schools, under the chairmanship of Sir William Goodenough. The assistance likely to be needed by medical schools in the future was one of the questions under review by that committee.

*Treatment by Unregistered Practitioners.*—On March 21 Mr. ALFRED EDWARDS asked the Minister of Health whether, when proposals for a national health service were drawn up, consideration was given to the fact that a number of people were treated by unregistered practitioners; and what was the outcome of such consideration. Mr. WILLINK replied that there was nothing in the proposals advanced by the Government which would prevent those who preferred to do so from seeking treatment from unregistered practitioners. The service itself, however, must clearly be based on registered medical practice in the form in which that had so far been approved by Parliament.

*Infant Mortality Inquiry.*—On March 21 Mr. JOHNSTON informed Major Markham that he had asked the Scientific Advisory Committee "to consider the factors specially responsible for that part of infant mortality attributable to infections, with particular reference to the first month of life, and to suggest means for reducing mortality from this cause." The personnel making this inquiry and the manner in which it should be conducted were for the committee to decide, but he had no doubt that all relevant information, including experience and developments elsewhere, would be carefully weighed.

#### Notes in Brief

In 1943 2,443 other ranks, who were in Category A1 on enlistment, were subsequently boarded out of the Army after serving for less than six months.

The amount of the grant-in-aid for the work of the Medical Research Council is £215,000 in the current financial year. The proposal to be submitted in the estimates for 1944-5 is for a grant of £250,000.

No. 10

## EPIDEMIOLOGICAL NOTES

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 11.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

\* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

## Discussion of Table

In England and Wales during the week the total cases of scarlet fever exceeded those of the previous week by 218. Acute pneumonia showed a similar increase of 195, measles of 111, and cerebrospinal fever of 37, while there were 57 fewer cases of diphtheria, and 10 fewer of dysentery.

A small rise in scarlet fever was general throughout the country, but particularly marked in Yorks West Riding and Nottinghamshire, where the totals were respectively 36 and 35 more than last week. The incidence of measles fluctuated within the counties: Kent's total was 117 higher than last week, Norfolk's 67, and Wiltshire's 60; and Gloucestershire's total dropped by 74, and Lancashire's by 51. The rise in pneumonia was most rapid in the counties of the west midland region, where there were 80 cases in excess of last week's total.

The notifications of dysentery, 208, remained at a high level. No new outbreak of any size was reported, and the largest returns were those of Surrey 27, Lancashire 26, London 23, Yorks West Riding 20, Middlesex 19, Sussex 10.

In Scotland an increased prevalence was recorded for measles with a total 88 higher than last week, acute primary pneumonia with a total 73 higher, whooping-cough with a total 39 higher, and scarlet fever with a total 33 higher, while the notifications of diphtheria fell by 33. In Glasgow the total notifications of measles rose by 100 cases, and those of pneumonia by 20; 20 of the 31 cases of cerebrospinal fever were recorded in this city. The largest returns of dysentery were Glasgow 12, Falkirk 11, and Edinburgh 10.

In Eire, notifications of measles and diphtheria fell slightly. In Dublin C.B., the incidence of measles was down by 49, but it rose by 38 in the rest of the country.

In Northern Ireland the incidence of scarlet fever rose to a total of 50 more than last week. The notifications in Belfast C.B. rose from 42 to 72.

## Smallpox

A further case of smallpox has been reported from Mount Vernon Emergency Hospital, Middlesex, making the total 12. A case of smallpox having occurred in Yorks West Riding, Pudsey M.B., the medical officer has decided that chicken-pox shall be a notifiable disease for one month.

## Week Ending March 18

The notifications of infectious diseases in England and Wales during the week included: smallpox 3, scarlet fever 2,395, whooping-cough 2,026, diphtheria 685, measles 2,226, acute pneumonia 1,284, cerebrospinal fever 87, dysentery 269, paratyphoid 5, typhoid 6. In the great towns there were 51 deaths from influenza.

## Points from Abroad

Siegmund (Klin. Wschr., 1943, 22, 763) observes that the disease process in epidemic hepatitis is based on that of an acute diffuse hepatopathy, associated with disturbed capillary circulation, altered permeability of the capillary walls, and consequent changes in the mesenchymatous and parenchymatous parts of the lobule. At an early stage the capillary walls are "loosened," the capillary membranes stretch, and the cells in the walls increase in size and number and often show lysis. The liver cells also soon become enlarged and show cloudy swelling. Holler says that the two common signs are diarrhoea and jaundice. In his opinion epidemic hepatitis is to be classified with those infections with a monocytic reaction. Beiglböck states that in epidemic hepatitis swellings of the lymph glands and enlargement of the liver and spleen are common. Jaundice is not a constant symptom. Histologically the picture is of a striking reaction of reticulo-endothelium and connective-tissue apparatus, accompanied by more or less comprehensive injury of the liver cells. In severe cases this may be accompanied by an increased capillary permeability. Transition into subacute liver atrophy on the one hand and into cirrhosis on the other hand occurs.

According to Vetter (Klin. Wschr., 1943, 22, 767), since 1938 there has been observed in Germany a new inflammatory disease of the conjunctiva and cornea which has assumed epidemic proportions hitherto unknown. Its course is divided into the stage of acute conjunctivitis and that of nummular keratitis. A typical sign in the first stage which is important for diagnosis is the palpable and often visible swelling of the regional (auricular and submental) lymphatic glands. The nummular foci present in the second stage, and always separated from each other by normal corneal tissue, can, however, also develop into confluent surface infiltrations which can very easily lead to desquamation of the epithelium, thus producing severe ulcer similar to ulcer corneae serpens. As a result of the formation of scars, visual disturbances often remain. In contrast to earlier observations, the disease also attacks children under 12 years, even 2-year-old infants.

## Medical News

Dr. Charles Hill will speak on the White Paper at a meeting of the Yorkshire Branch of the B.M.A. to be held on Sunday, April 2, at 2.30 p.m. at Philosophical Hall, Park Row, Leeds.

A meeting will be held on Wednesday, April 5, at 4.30 p.m. at Manson House, 26, Portland Place, London, W.1, to which all medical practitioners in St. Marylebone have been invited, to discuss by question and answer the implications of the White Paper. At least one prospective Parliamentary candidate and a Member of Parliament will be present, and Mr. W. McAdam Eccles will preside.

The British Council has for disposal several copies of each of the following publications: *Biological Surgery in Tuberculosis* (1942), *Biological Surgery in Bone-tuberculosis Patients* (1941), and *Lung Puncture as a Biological Treatment of Divers Localizations of Tuberculosis* (1942), all three by C. Robertson-Lavalle; also *Adecuación al Trabajo* (1943), by H. J. A. Rimoldi. Copies of any of the above will be sent gratis to practitioners, libraries, institutions, etc., on application to the Medical Department, British Council, 3, Hanover Street, W.1.

The Institute for the Scientific Treatment of Delinquency announces a course of twelve lectures on criminal law and administration, to be given by Mr. A. L. C. Morrison on Saturdays at 2.30 p.m., beginning April 15, at 17, Manchester Square, W.1. The fee for the course is £1, single lectures 2s. There will be no lecture on May 13 or May 27. Ten lectures on the historical background and present position of psychology are to be given by Prof. J. C. Flugel on Sundays at 5.30 p.m., beginning May 21. Fee for the course 17s. 6d., single lectures (only if seats are available) 2s. Further particulars may be had from the general secretary at the above address.

A series of "health weeks" have been held in all the factories in the Rootes group of companies, and the last will begin on April 24. Sir William Rootes, who takes a great interest in the welfare of the 40,000 people in the factories he controls, has inaugurated these with the object of reducing the amount of time lost through avoidable illness and to educate the worker in preventive medicine. The daily programme of events takes place in each factory canteen at lunch-time and during the night-shift break, and includes films and talks on a number of medical subjects; also demonstrations on the preparation of nutritious and palatable food. A special feature of the health weeks is an all-medical "brains trust."

Dr. John R. Williams contributes to the February number of the *Canadian Medical Association Journal* an account of the launching of the s.s. *Frederick Banting* at the Bethlehem-Fairfield Shipyard in Baltimore, Maryland. The ship, a Liberty, is 500 feet long and displaces 10,000 tons. Among those attending the ceremony from Toronto were President Cody of the University, Lady Banting, and Dr. Charles H. Best, and among those representing the Canadian Government was Ambassador Leighton McCarthy. The ship was christened in the traditional manner by Lady Banting, who said afterwards that of all the honours that had been conferred upon her husband she was sure this would touch him most. She presented a portrait of her husband to be placed in the cabin of the ship, and Dr. Best spoke feelingly of his association with Sir Frederick Banting. Mr. Bouslog said that in view of its broad implications of international good will, the U.S. Maritime Commission, which he represented at the launching, had decided to present the s.s. *Frederick Banting* to the British Government.

The Medical Consultative Committee appointed to act for the associated village settlements of Papworth and Enham, of which the hon. medical director, Group Captain R. R. Trail, M.D., is chairman, has set up a research committee to advise on the direction of medical research work at these settlements and to co-ordinate this work with other research investigations on tuberculosis in this country. The following have accepted invitations to serve on this committee: Sir Arthur S. MacNalty (chairman), Sir Joseph Barcroft, Prof. S. P. Bcdson, Dr. F. R. G. Heaf, Sir John Ledingham, Prof. W. H. Tytler, Prof. O. L. V. de Wesselow.

The Central Council for Health Education intends holding two summer schools during 1944. One will take place at Whitelands College, Bede College, Durham, from July 24 to Aug. 3, and the other at Chelsea Polytechnic, London, from Aug. 9 to 19. The programme will cover all aspects of health education (including sex education) and should be of value to teachers, youth leaders, educational and medical administrators, nurses and health visitors, social and industrial welfare workers, etc. Many applicants had to be rejected from the 1943 school owing to lack of accommodation. Those wishing to receive early notification of the forthcoming schools should send their name and address on a postcard to Mr. Cyril Bibby, Central Council for Health Education, Tavistock House, Tavistock Square, W.C.1.

## Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1. on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Atitlogu Westcent*, London; SECRETARY, *Mediseca Westcent*, London. ADVERTISEMENTS, *Articulate Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

### ANY QUESTIONS?

#### Protection against X Rays

Q.—Some people do x-ray work without adequate personal protection. What should the latter consist of, when screening or taking films?

A.—The first care of every practitioner approaching radiography and screening with unfamiliar apparatus is to familiarize himself with the normal functioning of the set for screening and radiography. In using it he must be prepared to accept the responsibility for the welfare of his patients and his technical assistants as well as for himself. Should trouble arise his work may be assessed on this presumption—that he has specialist training and experience.

Manufacturers and designers of x-ray apparatus have before them the National Physical Laboratory standard of protection, which guides them in securing a recognized standard of tube and apparatus safeguards, but the use of unorthodox technique and home-made modifications of the set may introduce grave dangers. It is therefore wise to put to oneself the following questions: Is the set of N.P.L. standard? Am I using correct technique and the set in the manner for which it was designed? Where any doubt exists as to the safety of the general working conditions the N.P.L. will, for an appropriate fee, carry out the necessary investigations. Special films can be obtained from the N.P.L., and these films can be worn on the person for the appropriate period and returned to the N.P.L.; from them can be ascertained the radiation exposure received in the area on which the film was worn.

The British X-ray and Radium Protection Committee was formed in 1921 for the express purpose of preparing recommendations to arrest the sequence of casualties to x-ray and radium workers; the sixth revised report (Feb., 1943) is readily available in printed booklet form, and can be obtained on application to the General Secretary, British Institute of Radiology, 32, Welbeck Street, London, W.1. All who use x rays or radium should be familiar with the contents of these recommendations.

A few general practical observations may not be out of place. The amount of work to be done is of course an important factor. With little work properly carried out the risk is proportionately less, but with misuse of present-day powerful apparatus irreparable damage may occur in a few minutes—one might even say seconds without exaggeration. With much work the danger-point may easily be reached, and it is all too true that familiarity breeds carelessness. The modern practice is to affix the protective material to the apparatus; even so, the lead-rubber apron may still be desirable. Lead-rubber gloves should be available for palpation and should be worn always by those who have occasion to contaminate their hands with iodine or other irritants, or frequently to "scrub up." All x-ray tubes should be provided with a filter equivalent to at least 1 mm. of aluminium. Distance is a great safeguard when diagnostic exposures (radiographs) are being made. Everyone should be as far away from the tube and the patient as possible, preferably behind a lead protection screen and behind the x-ray tube. Technical assistants and others present should be made to observe this principle during screening and radiography because there is a danger zone of secondary radiation all round the area of the patient that is being examined. The narrowest cylindrical diaphragm that will just "cut" the corners of the film size in use not only improves all radiographs but is a great aid to protection.

For screening, the room should be provided with a light-dimming switch so that preparation can be made in a progressively dimmed light, thereby economizing the time necessary to become fully dark-adapted. Red lighting is an alternative. It should not be possible for the eyes to meet an unshaded electric globe. The minimum screening current should be used at normal screening distances: 3 mA at from 60 to 75 kV is adequate; if it is not, then suspect your dark-adaptation. Resist the impulse to increase the

screening current; nothing is gained, and, in fact, much is lost, by over-illumination of the screen (some may doubt this, but it is a fact easy of demonstration). Intermittent screening—one or two seconds on and off—is a habit to be cultivated. The mechanical rectangular diaphragm should be closed down to the limits of the area under observation, and it should not be possible to open it to an area larger than the area of the fluorescent screen. Displacement of the tube in relation to the screen should be prevented by mechanical fixation.

According to the part under examination all screening should be approached with a definite set of questions to be answered and dealt with in a routine order; if this is done the screening time will be very much shortened. It is all too easy to leave the screen with as blank a mind as when one started. The manipulation of fractures and the removal of foreign bodies under "live" screen control should be absolutely taboo.

Protection lies in following the rules; copy not those who appear to break them.

#### Cold Agglutinins

**Q.**—In the most interesting and useful reply given to the question on influenza in the JOURNAL of Dec. 11 reference is made to cold agglutinins. Could we be told just what these are, and, what their clinical significance is?

**A.**—Cold or auto-agglutination is a rare phenomenon that may occur in a variety of conditions—e.g., haemolytic or other severe anaemias, paroxysmal haemoglobinuria, trypanosomiasis—and has lately come into prominence because of its frequent occurrence in primary atypical pneumonia. The phenomenon is apparently due to a true agglutinin which acts only when the blood is cooled to a low temperature; this agglutinin acts not only on Group O blood but also on the blood cells of the patient—i.e., it is an auto-agglutinin. Primary atypical pneumonia is an influenza-like infection characterized by a persistent unproductive cough and positive radiological findings in the lungs. The infection is not easy to diagnose without x-ray examination, and even with it may be simulated by influenza or bronchopneumonia, tuberculosis, and bronchiectasis. The presence of cold agglutinins would therefore serve as a useful method of diagnosing primary atypical pneumonia if constantly present in that infection and absent in other similar diseases. Turner and his colleagues (Lancet, 1943, 1, 765) have supplied evidence that this may be so. Thus, although cold agglutinins may be present in normal blood in low titre (up to a dilution of 1/16 of the patient's serum) they appear in much greater quantity in the blood of patients with primary atypical pneumonia and behave in this disease like a specific antibody—i.e., they develop about the tenth day of the disease and disappear in convalescence. For the test 2 to 3 c.cm. of patient's blood is taken off, the serum is separated, and falling dilutions of it are mixed with a 3% suspension of washed Group O human erythrocytes. The tubes are placed in the refrigerator overnight (2° to 5° C.) and read the next morning in the same way as the Paul-Bunnell test. Titres from 1/32 to 1/2000 are obtained. The reaction is reversible, as can be shown by placing the tubes in a water-bath or incubator at 37° C., when the clumping disappears. No satisfactory explanation of the phenomenon has yet been given.

#### Erythema Nodosum

**Q.**—What are the present views on the causation of erythema nodosum? If the streptococcus is believed to be an aetiological factor, should cases of erythema nodosum be treated with one of the sulphonamide drugs?

**A.**—Erythema nodosum is believed to be an allergic reaction to infection, most commonly by the tubercle bacillus or the haemolytic streptococcus. In from 10 to 30% of cases frank tuberculosis later develops, and erythema nodosum should always be the signal for a careful clinical examination, sputum test, and x-ray film of the chest; inquiry for contact; and subsequent supervision and x-ray examination of the chest at intervals. In the cases believed to be due to streptococcal infection there is often a history of a sore throat a week or ten days previously. By the time the skin lesion appears it is too late to use sulphonamide treatment, as the trigger of the allergic explosion has already been fired. The condition is strictly comparable with acute rheumatism, where sulphonamides are of no value in treatment, though they may be of great value in the prevention of attacks.

#### Testicular Pain

**Q.**—Can you suggest diagnosis and treatment for a man aged 48 troubled by painful swelling of the testes accompanied by lower abdominal pain of a dragging nature? If left alone it will subside in a few days, but will go immediately upon coitus or masturbation. Causes patient intense mental anxiety and worry.

**A.**—The pain in the testicles in this case is probably comparable with that complained of in certain cases of severe varicocele, and is related to congestion. In the present case, as in many others, it is relieved by intercourse, which in some poorly explained way acts as a method of decongestion. The disability which it causes is more mental than physical, but all methods tending to reduce congestion

are worth a trial. Thus a good suspensory bandage, and the administration of a saline purge, possibly combined with a glycerin suppository, would be of help.

#### Shutting Out Sound

**Q.**—A patient who has to do work requiring much concentration in noisy surroundings is anxious to obtain an ear appliance which will completely shut out sound. He has tried wax ear-plugs, but these were not sufficiently sound-proof. Can you suggest an alternative?

**A.**—There is no appliance which completely shuts out sound. Noise is made up of high and low frequencies which may peak at varying intensities. Ear appliances such as plugs and pads attenuate high frequencies of the spectrum to some extent but have comparatively little effect on low ones; consequently sound as such will still be heard. The over-all intensity is affected only to a limited extent. The attenuation of sound is dependent on the density of the substance interposed between the source of sound and the ear—a brick wall, for example, attenuates it more than a wooden partition. Most ear-plugs made of solid material are uncomfortable if one aims at complete occlusion of the meatus. If much concentration for work is necessary, then sound-proofing of the working surroundings is the only remedy. Fibrous plasticine or any such malleable substance moulded to fit the external auditory meatus so as to obtain a tight seal is the only alternative.

#### Congenital Deafness

**Q.**—Herewith a note of my patient's family history. Can you advise me what is the likelihood of her children being affected by deafness? My patient's hearing is apparently normal. She is engaged to be married, but is very anxious about the possible effect on any children of the marriage.

**A.**—The congenital deafness, or deaf-mutism, in this family group shows recessive inheritance, as is usual. The chances are two to one in favour of the patient being a carrier. In my opinion, however, this is not a ban to marriage provided that she does not intend to marry a blood relative on her father's side, or anyone with a family history of congenital deafness. With these exceptions the risk of a child being deaf should be only small—in fact, little greater than the risk of a recessive defect of some kind or other turning up in any marriage; for most of us, if we but knew it, are, in all probability, carriers of at least one such defect.

#### U.V.L. for Rickets

**Q.**—What are the present views on the use of ultra-violet light (quartz mercury vapour lamp) in (a) the prevention and cure of rickets, (b) for prophylaxis in children in comparatively sunless areas? (c) Is there any evidence that U.V.L. is carcinogenic, and (d) what is your opinion on the statement that "there is no definite means of measuring the dosage"?

**A.**—(a) The antirachitic properties of ultra-violet rays of the appropriate wave band (2,400 to 3,100 A.U.) are not in doubt. It is, however, conceivable that their application to the human skin may be futile if this does not contain those substances from which vitamin D is elaborated. Nor is it effective where the corneal layer is so thick or dirty as to prevent penetration of the rays. (b) Man was not intended to exist in the absence of sunlight, but some measure of adaptation is clearly possible. For those who fail to adjust themselves to reduced sunlight—particularly when dietetic provisos are satisfied—artificial light constitutes an excellent prophylactic. Some authorities rightly regard indiscriminate irradiation in the absence of indications as an error, on the grounds that the tolerance to radiation is increased and that this may detract from the efficacy of application when indications do arise. (c) Although the lethal action of U.V.R. on living cells results in the liberation of substances which provoke proliferation of cells, there is no conclusive evidence that when it is used in therapeutic dosages the proliferation ever assumes malignant qualities. (d) It is incorrect to state that "there is no definite means of measuring dosages." With elaborate physical equipment it would be quite possible to say at the end of a treatment: "X ergs or calories of a radiation

of Y wave-length have been allowed to impinge on this patient's skin." A similar statement would have to be made for every other wave-length employed. This would constitute a quantitative measurement of the dosage. How much of the radiation would be effective is another problem. The cost of the apparatus required for such a computation and the time required for it would offset the meagre practical return that would accrue.

#### Appointment of Coroners

**Q.**—*What system governs appointments to the office of coroner—i.e., by whom are such appointments made, are they advertised, or is it customary to appoint the deputy already in office? How are coroners nominated, and what are the limits of income available from their office? Is any preference shown to an applicant with a legal qualification over one who is medically qualified? Are any such appointments given only to applicants possessing both medical and legal qualifications?*

**A.**—A county coroner is appointed by the county council, a borough coroner by the borough council (Coroners (Amendment) Act, 1926, s. 2). If the district of a county coroner is wholly within a county borough the appointment is made by the council of that borough (Coroners Act, 1887, s. 33; Municipal Corporations Act, 1882, s. 34 (4)). There still remain a few franchise coronerships, but with certain exceptions Sect. 4 of the 1926 Act provides for their abolition and absorption in the county when a vacancy occurs. An appointing authority is not obliged by law to advertise a vacant coronership, but it is customary to advertise in the legal and medical press. There is no recognized practice of appointing the deputy already in office, but naturally it is a convenient way of training a new coroner. Coroners are remunerated by salary paid by the appointing authority under Sect. 5 of the 1926 Act, and they receive pensions (Sect. 6). The salaries of most of the surviving franchise coroners are paid by the county council. The salary paid to each coroner in the country will be found in Table XXXII of the volume of criminal statistics for 1938 (Cmd. 6167). The report for 1936 of the Departmental Committee on Coroners (Cmd. 5070), para. 16, also gives some information about the range of coroners' salaries. The pay of a deputy coroner is arranged between the coroner and deputy; the coroner's salary covers travelling and other incidental expenses, and the payment of a deputy is one of the matters which the appointing authority takes into account in fixing it. The 1926 Act, Sect. 1, requires that a coroner appointed since it became law shall have legal or medical qualification. In 1936, of the 309 coroners in England and Wales 268 were barristers or solicitors, 37 were medical practitioners, and 4 had no professional qualifications. A few of the barristers and solicitors also possessed medical qualifications (see the report on coroners (supra), paras. 11 and 13). This report contains further information on the law and practice concerning coroners, and the questioner may also refer to Jervis on *Coroners*, 7th ed., 1927, and other standard textbooks.

## LETTERS, NOTES, ETC.

#### Certification and Secrecy

**Dr. J. H. YOUNG** (Leigh, Lancs) writes: The recent correspondence on professional confidence prompts me to report a case which occurred recently in my practice. A patient employed by the Ministry of Works was found to be suffering from pulmonary tuberculosis. His employers demanded a certificate of disability. On this I merely stated "illness." The Ministry insisted on knowing the nature of the complaint and would not listen to my explanation that professional secrecy forbade such a disclosure. Eventually "for the sake of fear" the patient, in a written declaration, asked me to disclose the nature of his illness. I refused to do so without such sanction, an attitude in which, I am glad to say, I received the support of the Medical Defence Union. Surely it is time the profession made a stand against such demands from employers. I must state, however, in all fairness that the majority of employers in this district appear to be satisfied with the word "illness" (or "accident"). It is not difficult to imagine embarrassing circumstances arising on frequent occasions if we are always to inform employers the nature of a patient's illness.

#### Thymus and Death under Anaesthesia

**Dr. W. J. MOORE** (Glasgow) writes: The question on the thymus and death under anaesthesia (Feb. 19, p. 277) interested me, as many years ago I introduced what I have called fractional electro-coagulation of the tonsils of such patients, and I have now dealt successfully with many cases. As a matter of fact I have just finished with a child of 5 who had very large tonsils; but from the point of view of his cardiac condition and a very prolonged coagulation time I felt it was unwise to attempt anything in the nature of radical operation. My first case was that of an adult over twenty years ago. Admitting that the treatment requires at least from six to twelve sittings the attempted results so far have been very desirable. I have not the slightest doubt that if this technique were adopted the

tonsils would be very satisfactorily dealt with. I have seen various forms of treatment mentioned tried, but without success during the times I was assistant to the late Dr. John McIntyre have written several papers, but so far have not published any relative to the tonsils, although I had intended making a communication on them at an early date.

#### Fröhlich's Syndrome

**Wing Cmdr. H. M. STANLEY TURNER** writes: I do not quite know the answer in "Any Questions?" to the query on this (Feb. 12, p. 242). Fröhlich's syndrome should be distinguished from pre-puberty infantilism, which it resembles so closely in appearance. The difference is that in the latter condition (most of the cases have been in girls) menstruation appears, the adipose tissue decreases, and there is a normal development of secondary characteristics without the need for physiological stimulation. Therefore I should be inclined to wait until the child reaches the age of or even 15, to give normal puberty a chance, rather than give stimulation at too early an age. Some of the subjects of pre-puberty infantilism show degenerative changes in the ovaries when they reach adult life. One of my cases suddenly developed all the signs of perforated appendix, a diagnosis confirmed by the surgeon. At the time the abdomen was opened the peritoneal cavity contained a quantity of blood, due to haemorrhage into and rupture of one of the right ovary, about as big as a small orange.

#### Mercurial Poisoning

**Dr. DAVID HALER** (London, W.1) writes: In your reply of March 11 (p. 381) to an inquiry about the danger of mercurial poisoning arising from the prolonged use of salyrgan or mersalyl you give a list of toxic symptoms. It is worthy of note that you do not mention sudden death, which may occur with incredible speed during the intravenous injection of these mercurials. The mechanism of this unfortunate result appears to be obscure, but it is probably a greatly increased risk in chronic nephritis. At least one fatal case was described in the *Lancet* in a single communication in 1943. I personally have seen another case also in 1943; in this instance the patient was a chronic nephritic, and necropsy findings were characteristic only of that disease. Even though these cases do not appear to be very common, still they were sufficiently important to justify your noticing them among the various dangers of the therapy.

#### Faints in Blood Donors

**Dr. FRANCES M. TAYLOR** (Ambleside) writes: In the report to the Medical Research Council on fainting in blood donors (*Journal*, Feb. 26, 1944) no mention was made of the height of the blood pressure. I have the impression (gained only from general practice) that a large proportion of those persons who faint, or feel faint during bleeding are those with a systolic blood pressure of 120 mm or under. It would be interesting to know if any systematic observations on this point have been made.

#### Nausea and Vomiting of Pregnancy

**Dr. A. R. MONTGOMERY** (London, N.4) writes: The answer to a question in the *Journal* of March 4 (p. 346) states that none of the numerous remedies advised has proved satisfactory. As I have found coramine (oral) and benzedrine tablets very useful in this distressing complaint, I should be interested to know whether others have tried either of these preparations. Nausea and vomiting of pregnancy is often associated with a lowered blood pressure, and it was this association which suggested the use of stimulating drugs. Coramine gives an immediate effect, while benzedrine can be taken as a prophylactic first thing in the morning. It should not be necessary to emphasize that other possible causes are taken into consideration and dealt with as required. Good results have also been obtained in related conditions—e.g., sea-, car-, and air-sickness.

#### Silicosis in a Chert-miner

**Dr. C. W. EVANS** (Bakewell) writes: In November, 1942, I published an article by me on silicosis in a chert-miner. I have recently had another case which is of some interest. The patient died from silicosis and tuberculosis at the age of 45. He had worked in chert for 20 years in a Bakewell mine. There was no family history of tuberculosis. The lungs post mortem showed definite nodules of silicosis as well as extensive tuberculous changes. There had been a very considerable degree of cyanosis and edema in this case for the past two years. This is apparently the first case of silicosis proved post mortem by sections, although my former patient—the patient is still alive—has been acknowledged by the Medical Board as being due to chert by x-ray findings. Of course I am only referring to silicosis which has chert as the cause. There is one other interesting point in this case. The widow has refused to accept compensation because a claim was not made within five years of his leaving the mine. In point of fact the diagnosis of silicosis was not made until radiographs were taken by Dr. Hugh Macdonald at the Matlock Tuberculosis Clinic, where the patient was referred for the treatment of tuberculosis. My thanks are due to Mr. Harding of Sheffield for sections of the lungs.

LONDON SATURDAY APRIL 8 1944

SYMPTOMLESS INCOMPATIBLE TRANSFUSION AND RESULTANT CHANGES  
IN ISO-AGGLUTININ TITRE

BY

R. DRUMMOND, M.R.C.S.

*Transfusion Officer, Welsh Board of Health; Late Assistant Lecturer in Pathology, Welsh National School of Medicine, Cardiff*

Compatible blood transfusions in which studies of iso-antibody titre have been made are not numerous. The number of these mishaps reported in the literature is not a reflex of their incidence. In the case here reported blood-pumping technique was impeccable. The mishap, mercifully without any consequences, occurred for a different reason—namely, scrupulous care was not taken to see that the correct type of blood was obtained from the blood bank. The instances were somewhat similar to those in Mollison's (3) Case 10, in which effete group O blood was given to a group A recipient. After 19 days in cold storage the blood was left on a shelf at room temperature for four weeks. The nurse sent to fetch the blood selected this bottle instead of the correct one in the refrigerator. An hour after transfusion there was haemoglobinuria but no surviving donor cells. A febrile reaction occurred, but no further sequelae were noted.

## Previous Reports

Wiener (1937-8) studied a group O recipient who recovered after receiving 500 c.c.m. of group A blood. In preliminary tests the recipient's serum did not agglutinate the donor's cells. The biological test of Oehlecker (1921) was negative. Haemoglobinuria, jaundice, oliguria occurred. Two days later the anti-A titre was 20. It fell to 200 in the fifth week and fell to 70 in the ninth week. A group A haemolysis was detected. Wiener (1939) and Wiener (1941) studied a group O recipient transfused with 500 c.c.m. of group B blood. Rigor and haemoglobinuria resulted. In a few days the anti-B titre was only 1, but on the thirteenth day it was 10. Wiener (1941) investigated a group B recipient who recovered after receiving 150 c.c.m. of group AB blood. Rigor and haemoglobinuria occurred. Shortly after transfusion the anti-A titre for agglutination was 4 and for A<sub>2</sub> cells 0. A peak of 512 was attained on seventh day against A<sub>2</sub> and A<sub>1</sub> cells. Mollison and Young (1941) observed a group O air-raid casualty transfused with citrated group B blood (content, 360 c.c.m. whole blood) and unpooled group A sera. Group O blood and pooled plasma were also given. A febrile reaction occurred after transfusion. Eight hours after the incomplete transfusion the anti-A titre was 128, but some hours later it was only 32. The anti-B titre fell as low as 2. There was a subsequent colossal rise in titres. On the eighth day the anti-B titre was 500,000, and on the eleventh day the anti-A titre was over 100,000. Return to normal was slow. Rise in anti-A titre was due to group A substance in the transfused unpooled group A sera. Agglutinates were present in the recipient's blood for seven days after the incompatible transfusion. A haemolysis acting on A and B cells was observed from the seventh to twenty-fifth days. Anti-M and anti-N were not involved. Rises of anti-A titre to 16,384 and 100 were observed by Mollison (1943) in two group O recipients transfused respectively with 45 c.c.m. and 1,000 c.c.m. of group A blood; both recovered.

Certain workers, apart from those mentioned, used differential agglutination to study the *in vivo* survival of incompatible erythrocytes. Jervell (1924) reported the following cases. (i) A newborn child with megalena neonatorum. It was group O, but the  $\alpha$  and  $\beta$  agglutinins were absent. It received 100 c.c.m. of group A blood from its mother. The donor's cells survived six weeks. The mother's  $\beta$  agglutinin was detected in the child's serum for two weeks, and attained a titre of 10 on the second day. (ii) A group B child transfused with 600 c.c.m. of group O blood and 600 c.c.m. of group A blood. After being jaundiced she recovered. All

group A cells were eliminated in 12 hours. (iii) A group B female given 550 c.c.m. of group O blood and 350 c.c.m. of group A blood. She had a severe reaction, and died three hours later. The recipient's serum agglutinated the donor's cells to 1:4 and completely haemolysed them in 15 minutes. Blood taken by cardiac puncture 10 minutes after death showed marked haemoglobinuria and no surviving group A cells. (iv) A 2-year-old child, group O, afflicted with leukaemia, given 200 c.c.m. of group A blood. Drowsiness, vomiting, bloody urine, and jaundice occurred. Improvement followed transfusion of 200 c.c.m. of group O blood. The group A cells survived three days. In Lauer's (1941) case, immunization of a group O person to cells of another person (group A) occurred in a skin-graft operation. The anti-A titre was 2048 and later fell to 2. Burnham's (1930) patient, group B, recovered after transfusion with 400 c.c.m. of group A blood. Symptoms were mild. The recipient's serum agglutinated group A cells at room temperature but not at all at body temperature. The donor's cells survived three to five days. Grove and Crum (1930) investigated a group O recipient transfused with 300 c.c.m. of group B blood. No reaction occurred, and this was attributed to inability of the recipient's serum to agglutinate 2% suspensions of A or B cells in test-tubes, after incubation at 42° C. for one hour. The donor's cells were surviving the day after transfusion. The recipient's blood was not further examined till the seventh day, when no donor's cells were found.

Schiff (1924) produced a specific precipitin in rabbit serum against agglutinin-A substance in human serum. Aubert, Boorman, and Dodd (1942) extended Schiff's work. They injected Seitz-filtered human A or B sera into guinea-pigs or human volunteers, and produced anti-A or anti-B antibodies, some of quite high titre. Alternate responses were produced in a group O subject by injecting first group A and then group B serum. Rises in iso-agglutinin titre after incompatible transfusion, while principally due to agglutininogen in incompatible cells, may therefore in part also be due to agglutininogen substance in solution in the donor's plasma.

## Case Report

In the case here recorded the iso-agglutinin changes were studied and an attempt was made to find an *in vitro* explanation for absence of symptoms.

A man aged 54 was admitted to hospital on Feb. 19, 1943, for melena and loss of weight. He was crippled by chronic rheumatoid arthritis, which was still active. Seventeen months ago he had a course of gold salt injections. Seven years ago he underwent an operation for gastric ulcer. Later pain had occurred in the epigastrium after meals and was relieved by taking food. Weight 8 st. 10 lb.; blood pressure, 120/60; blood count—red cells 4,000,000, leucocytes, 7,600; haemoglobin, 40%; blood group, 1 and Rh-positive. On March 22 the haemoglobin was 60%.

On March 23 the patient was inadvertently transfused with group A blood under the following circumstances. The local issuing blood depot was requested to supply group B concentrated red cells. After cross-matching tests the blood was issued and placed in the hospital blood bank. The medical officer in charge of the case instructed a nurse to fetch the blood from the refrigerator. A bottle of blood was selected and given to the medical officer. The bottle label was not examined, and transfusion was started at 6 p.m. at a very slow drip rate. Some 5½ hours later it was noticed that the bottle was labelled group A. The patient had complained of no symptoms whatever. Transfusion was immediately stopped. Approximately 460 c.c.m. of blood had been transfused. The blood mixture consisted of 120 c.c.m. of 2.5% sodium citrate solution, 20 c.c.m. of 10% glucose solution, and 400 c.c.m. of whole blood

The blood had been stored for seven days under proper conditions. The remnant of blood in the bottle was checked and found to be group A, and the cells were agglutinated by the recipient's serum, a specimen of which was collected at the time. The recipient's group was confirmed as B. The group B blood supplied for the recipient was still in the hospital blood bank.

No febrile reaction occurred during transfusion, when the pulse was 76 and temperature 97° F. Six hours later the pulse rose to 102 and the temperature to 100° F. However, the patient felt well. The temperature was normal within 12 hours, and thereafter remained normal or subnormal. In 24 hours the pulse dropped to 76. The recipient had run an occasional pyrexia since admission, and the day before transfusion the pulse was 100. On March 24, some hours after transfusion, 300 c.cm. of 2.5% sodium citrate solution was injected intravenously. Potassium citrate gr. 60 was given hourly by mouth till the urine was alkaline. Intravenous glucose-saline was given at a slow drip rate. General condition satisfactory. Over 24 hours the fluid intake was 94 oz. and output 123 oz. Serum bilirubin, 0.1 mg. per 100 c.cm.; icterus index, 3.3. Trace of urobilin in urine.

**March 25.**—Condition satisfactory. Temperature and pulse normal. Urine normal and no casts or erythrocytes in centrifuged deposit. No haemoglobinuria. The serum of the venous blood was clear; there was neither bilirubinaemia nor haemoglobinuria. During 24 hours the fluid intake was 149 oz. and the output 125 oz. Intravenous glucose-saline discontinued.

**March 26.**—I was asked to make investigations. The patient's complexion was ruddy and his general condition good. No jaundice. Closely interrogated as to whether he had felt any untoward symptoms during the transfusion, he replied confidently in the negative. Indeed, he asserted he felt better for it. Ever since admission to hospital he had had a more or less constant dull aching pain in the dorsal region of the back, and in the ankle- and knee-joints. These symptoms had been present for months. Backache was present all day before transfusion and was in no way worse during or after it. The backache was still present months later. Urine normal and nothing abnormal in the centrifuged deposit. Blood urea, 40 mg./100 c.cm.; icterus index, 4; serum bilirubin, 0.1 mg./100 c.cm. Temperature and pulse normal. Although untoward symptoms were absent, it was decided to take anticipatory measures. Transfusion of compatible blood as recommended by Hesse and Filatov (1932) and Hesse (1936) was advised in combination with preliminary phlebotomy of the recipient. Von Deesten and Cosgrove (1933-4) employed phlebotomy with good result for uraemia due to haemolysis after blood transfusion. Withdrawal of 500 c.cm. of recipient's blood was made by venepuncture and promptly followed by transfusion of 540 c.cm. of group B whole blood (stored in mixture already alluded to). No febrile reaction. During 24 hours the fluid intake was 152 oz. and output 125 oz.

**March 27.**—The patient had some slight transient pain on breathing. Withdrawal of 420 c.cm. of recipient's blood and transfusion of 540 c.cm. of group B blood. No reaction. Blood urea, 32 mg./100 c.cm.; serum bilirubin, 0.3 mg./100 c.cm.; icterus index, 5. Fluid intake 150 oz. and output 103 oz. **March 28.** No untoward symptoms. Withdrawal of 420 c.cm. of recipient's blood and transfusion of 540 c.cm. of group B blood. No febrile reaction. Fluid intake 104 oz. and output 97 oz. It was noted that the plasma of the recipient's blood withdrawn on the previous day had a peculiar slightly greenish tinge. **March 29.** Withdrawal of 420 c.cm. of recipient's blood and transfusion of 540 c.cm. of group B blood. No reaction. Fluid intake 110 oz. and output 107 oz. Urine normal. Haemoglobin, 66%; blood urea, 31 mg./100 c.cm.; serum bilirubin, 0.05 mg./100 c.cm. **March 31.** Condition satisfactory: haemoglobin, 68%. **April 1.** Urine contained a few granular casts and trace of urobilin. **April 2.** Blood urea, 40 mg./100 c.cm. **April 22.** Haemoglobin, 74%; patient left hospital.

He was observed for several months, and except for the arthritis remained well. There are no grounds for assuming that the bleeding of the recipient and transfusions of homologous blood contributed to the favourable outcome.

#### Special Investigations of Case

Regrettably, in the 48 hours immediately after incompatible transfusion no investigation for methaemalbumin, Schumm's test, or spectroscopy for serum haemoglobin was made. Fortunately a pre-transfusion specimen of the recipient's serum was available at the local issuing blood depot. This specimen was collected the day before the incompatible transfusion. This serum strongly agglutinated the conserved red cells of the donor's blood (now 10 days old). The technique was to mix equal volumes (0.4 c.cm.) of saline, citrated red cell suspension (strength 0.5%), and serum in tubes of 3/8 in. diameter. After standing five minutes at room temperature tubes were centrifuged at 2,000 r.p.m. for two minutes. The groups of recipient and donor were confirmed as B and A respectively. Tests were performed in tubes, and groups were checked on cells and serum. The donor's plasma agglutinated the recipient's cells

weakly. The above results likewise obtained at 37° C., whether tubes were stood five hours or centrifuged. The recipient's serum was diluted 1:25 (i.e., 1 c.cm. serum to 24 c.cm. saline) and titrated against cells of a standard A donor (subgroup A<sub>1</sub>); the titre was 1:100 at room temperature.

The titration technique was similar to that of Challinor, Ives, and van Rooyen (1939). Volumes of 0.4 c.cm. were used. Serum dilutions were doubled in saline from tube to tube. Tubes were 3/8 in. by 2 in. The washed citrated fresh red cell suspension was packed by the centrifuge to a strength of 0.5% in terms of cell sediment. The titre was stated as the greatest dilution in which agglutination was observed. Dilution caused by addition of the volume of red cells was taken into account, though many workers ignore this. Tubes, including controls, were stood five hours at room temperature and then examined for agglutination after adequate flicking with the index finger. The end-point observed by the naked eye was noted, and in succeeding tubes agglutinates were sought for by microscopy. Clumps of 3 to 5 cells were taken as evidence of agglutination. The end-point observed by microscopy was invariably one or two tubes, occasionally three, higher than that noted by the naked eye. Tubes were adequately shaken so as to avoid false positive readings. This precaution is necessary, since if a suspension of red cells in citrate or saline is allowed to settle and is then microscopically after inadequate shaking, agglomerates of cells may sometimes be observed. Such agglomerates may be quite large and resemble clumps of agglutinated corpuscles. Too vigorous agitation may, however, eliminate evidence of agglutination in the higher dilutions. Titrations were done in duplicate.

The recipient's serum taken the third day after incompatible transfusion agglutinated the conserved donor cells only to a titre of 1:16. Identical results were obtained with fresh cells from the incompatible donor and from a standard A donor (subgroup A<sub>1</sub>). Hereafter the titre rose rapidly and attained a peak of 1:25,600 on the fifteenth day. The titre fell slowly, and eight months later had not quite approximated the pre-transfusion level (see Fig. 1). In

FIG. 1.—Transfusion of a group B recipient with group A blood. The curve shows the initial fall, rapid steep rise, and slow fall of the anti-A titre.

FIG. 2.—Agglutinates of group A cells surviving in the blood of the group B recipient on the third day after incompatible transfusion.

all titrations the same group A donor was used as standard. It was not possible to obtain blood regularly from the incompatible donor. No haemolysis was detected in the recipient's serum; this is in contrast to the observations of Jervell, Rö, and Mollison.

On the third day after the incompatible transfusion 2 c.cm. of the recipient's blood was mixed with 1 c.cm. of citrate solution and allowed to stand till sedimentation was complete. Using a red cell counting pipette, some red cell sediment was drawn up to the mark 0.5, and then citrate solution up to the 101 mark. After mixing, a

few drops were expelled on to a glass slide and examined with a microscope. Agglutinates consisting of 20 to 30 cells were seen lying free among large numbers of unagglutinated cells and were hardly affected by a strong anti-A serum. The red cell sediment, however, was solidly agglutinated by a strong anti-B serum. These observations were confirmed by Prof. J. B. Duguid, who kindly took the photomicrograph (Fig. 2). Four days after incompatible transfusion only a few small agglutinates were found among the recipient's cells, but none were found on the fifth day.

In an attempt to find an *in vitro* explanation for the absence of symptoms, the following investigations (Tests I to IV) were made about eight months after the incompatible transfusion (Nov. 18).

TEST I.—The Incompatible Donor's Serum (anti-B) was Tested for Potency by Titration against the Cells of the Recipient and Cells of Random Group B Persons

Serum	Cells of Group B Persons	Titre					
		2	4	8	16	32	64
Incompatible group A donor	Recipient	++	++	++	++	+	0
	3200 ..	++	++	++	++	+	0
	11623 ..	++	++	++	++	+	0
	11624 ..	++	++	++	++	+	0
	11625 ..	++	++	++	++	+	0
	11626 ..	++	++	++	++	+	0
	11647 ..	++	++	++	++	+	0
	11652 ..	++	++	++	++	+	0

++ = Agglutinates visible to naked eye. + = Agglutinates visible only on microscopy. 0 = No agglutination.

TEST II.—The Recipient's Serum, Diluted 1:10, was Tested for Potency by Titration against the Incompatible Donor's Cells and Cells of Random Group A Persons

Serum	Cells of Group A Persons	Titre						
		20	40	80	160	320	640	1280
Recipient group B	Incompatible donor	++	++	++	+	?	0	0
	Standard donor ..	++	++	++	+	0	0	0
	11623 ..	++	++	++	+	0	0	0
	11624 ..	++	++	++	+	0	0	0
	11625 ..	++	++	++	+	0	0	0
	11626 ..	++	++	++	++	+	+	+
	11640 ..	++	++	++	++	+	0	0
	11646 ..	++	++	++	++	+	0	0
	11647 ..	++	++	++	++	+	0	0
	11654 ..	++	++	++	++	+	0	0

TEST III.—The Incompatible Donor's Cells (Group A) were Tested for Sensitivity against Sera of Random Group B Persons

Sera of Group B Persons	Cells	Titre							
		2	4	8	16	32	64	128	256
3200 ..	Incompatible group A donor	++	++	++	++	++	+	+	0
11623 ..		++	++	++	++	++	+	+	0
11624 ..		++	++	++	++	++	+	+	0
11625 ..		++	++	++	++	++	+	+	0
11626 ..		++	++	++	++	++	+	+	0
11647 ..		++	++	++	++	++	+	+	0
11652 ..		++	++	++	++	++	+	+	0

TEST IV.—The Recipient's Cells (Group B) were Tested for Sensitivity against Sera of Random Group A Persons

Sera of Group A Persons	Cells	Titre									
		2	4	8	16	32	64	128	256	512	1024
11628 ..	Recipient, group B	++	++	++	++	++	++	++	++	++	++
